Water-Contaminated Wounds

Aeromonas hydrophila
Pseudomonas spp.
Many gram-negative enteric organisms
Edwardsiella tarda (catfish injury)
Mycobacterium marinum

performed primarily, and signs of infection generally are not present. Days later, the clinician often is faced with the dilemma of a patient who is receiving antimicrobial prophylaxis with broad-spectrum agents and in whom new signs or symptoms develop acutely. Separating infectious from noninfectious complications often is difficult; however, the onset of fever in such a patient, especially in the setting of an open fracture or dural tear, should prompt further evaluation. Careful serial examination of the site of injury is necessary, and more extensive evaluation generally is indicated. Such assessment may include radiographic imaging and specific evaluation of body fluids with appropriate cultures. Because open fractures are associated with an increased risk for development of infection, the utility of antibiotic-impregnated implants, which are biodegradable and osteoconductive, may prove beneficial in such cases.^{135,141}

Infections associated with foreign bodies such as wood generally cannot be cured until the foreign body is identified and removed.¹⁴³ Puncture wounds should be explored carefully, and further debridement of necrotic tissue or drainage of involved sites such as joints may be necessary.⁸

Treatment of simple wound infections associated with soil or water contamination should include an agent such as ciprofloxacin, although deeper tissue infection may develop after a seemingly innocuous injury, and tissue debridement may be necessary. Determining the appropriate therapy for a patient with infection involving extensive soft tissue injury and open fractures is problematic. Administration of an empiric regimen with an agent such as piperacillin-tazobactam, imipenem, or a fluoroquinolone plus vancomycin may be reasonable after evaluation and appropriate culturing have been done.

60B ■ Viral and Fungal Skin Infections

Meena R. Julapalli • Moise L. Levy

VIRAL INFECTIONS

Cutaneous manifestations of viral infections are common. Exanthems often accompany acute viral infections. This chapter focuses on the common viral illnesses that manifest with cutaneous manifestations. More detailed information on each of these illnesses can be found in the chapters devoted to specific viral agents.

Viruses can invade the skin indirectly as a result of viremia or directly, as with warts, molluscum, or infections due to herpes simplex virus (HSV) or varicella-zoster virus (VZV). Other mechanisms of producing exanthems include interactions between the infecting agent and humoral or cell-mediated factors, systemic immune response in the absence of viral antigen in the skin,^{1,75} or medications as in the drug reaction with eosinophilia and systemic symptoms (DRESS).¹ Human herpes virus-6 (HHV-6) reactivation in DRESS appears to be associated with more severe disease.¹

The type of exanthem encountered depends on the virus, the pathophysiologic mechanisms involved, the location of the eruption, and local and systemic immune factors. A single virus may manifest with a variety of cutaneous reactions within the same host. Clinicians caring for a patient with an exanthem usually are faced with a challenge to determine its cause. Most viral exanthems are benign and self-limited, but understanding the exact cause can be important when evaluating immunocompromised patients or in the setting of exposure of a pregnant woman. Similarly distinguishing a viral exanthem from skin eruptions caused by other infectious agents or drugs is important.

Generally children presenting with fever and a rash cannot be diagnosed accurately by the presentation of the eruption.³³ The distribution and character of exanthems, such as the often characteristic reticulated erythema after “slapped cheek” exanthem typical of parvovirus B19 infections, are helpful; however, the virus can manifest with several other cutaneous findings.^{11,54,60} Typical hand, foot, and mouth syndrome is caused by coxsackievirus, although it has been related more recently to enterovirus 71 and other etiologies.^{15,42,49,51,58} The concurrent administration of antibiotics in the setting of Epstein-Barr virus infection is important to know, as is the possible relationship between HHV infection and certain drugs resulting in drug rash with eosinophilia and systemic symptoms.¹⁷

Laboratory studies, in addition to specific viral cultures, polymerase chain reaction, and serologies, may be helpful in distinguishing between viral and bacterial diseases or drug eruptions. Coagulation studies may help clarify whether a purpuric eruption is caused by a primary coagulopathy or a viral process. Other laboratory tests, such as streptococcal screens or throat cultures or both, serum antibody titers, viral cultures, and antigen detection methods, are required for evaluating exanthems depending on the state of the patient being evaluated.

Warts

See Chapter 152.

Molluscum Contagiosum

Molluscum contagiosum represents a common viral infection of the skin (and sometimes mucous membranes) of children and adolescents. It is caused by a poxvirus and has not been grown in culture although mapping of its genome has been done recently.⁵⁵ The virus replicates within the cytoplasm¹⁹ and is represented by four viral types based on DNA analysis: MCV-1 to MCV-4.⁵⁰ MCV-1 accounts for more than 90% of infections in the United States.^{19,50} The subtypes do not show site specificity. MCV-2 was reported to be seen most commonly in patients infected with human immunodeficiency virus (HIV).^{21,50}

Epidemiology

The disease is seen with increasing frequency in sexually active and immunodeficient individuals. Infection occurs at any age, with the highest frequency seen in patients younger than 5 to 10 years.^{10,19} The

FIG. 60B.1 Grouped dome-shaped papules of molluscum contagiosum on the skin of the abdomen.

disease is two to three times more common in school-aged and sexually active males than in females. Transmission is via close contact. Spread is reported to occur via fomites. The incidence of disease is highest in warm climates and in areas of overcrowding.

Clinical Manifestations

The incubation period for molluscum contagiosum is 2 to 7 weeks, but it has been reported to occur at 1 week of age. Typical lesions are 1 to 5 mm, dome-shaped, skin-colored or pink papules with a distinctive central umbilication (Fig. 60B.1). Giant lesions measuring 1 to 2 cm can be seen. According to an epidemiologic survey conducted at three pediatric dermatology centers, fewer than 15 lesions usually are seen.¹⁹ In children, molluscum contagiosum is seen most frequently on the face, neck, trunk, and extremities but may be seen on any part of the body, including the mucous membranes.^{10,19,45} Periocular lesions may lead to secondary keratoconjunctivitis or trachoma. In some cases, molluscum contagiosum is a sexually transmitted infection, raising the issue of sexual abuse when infection is seen in the genital area. The most common etiology of genital molluscum contagiosum is autoinoculation; however, if the lesions occur solely in the genital area or a question exists about the patient's social situation the possibility of abuse should be explored.

Atypical lesions of molluscum contagiosum are seen more commonly, particularly with the improved survival rates of patients with acquired immunodeficiency syndrome (AIDS) and other immunocompromised states. The incidence of molluscum contagiosum in HIV infection is 5% to 18%. With improved antiretroviral therapies, molluscum contagiosum has decreased in this population.^{12,19}

Molluscum contagiosum lesions in immunocompromised patients often are large, are situated more deeply in the epidermis, and may number in the hundreds. HIV-positive adults usually have molluscum contagiosum on the face, neck, and trunk. In a study of immunocompromised children, molluscum contagiosum was not considered to be common or severe, however. This study included only six patients, and two were disease free and thought to be immunocompetent at the

time of onset of the infection. This and other studies suggest that the presence and degree of cellular immunodeficiency are important in the presentation of molluscum contagiosum. Severe disease is known to occur in the setting of DOCK 8 deficiency.¹⁴

Patients with atopic dermatitis may be predisposed to develop more severe molluscum contagiosum infection. Available information is insufficient to know if this development is related to the dermatitis itself with its well-described barrier dysfunction or to the use of corticosteroids or other topical agents. The term *molluscum dermatitis* is used to describe an eczematous eruption, more commonly seen in patients with atopic dermatitis, which may occur around molluscum contagiosum lesions and is thought to represent a delayed-type hypersensitivity reaction to viral antigens in the dermis.

Molluscum contagiosum infections in healthy individuals usually resolve spontaneously over the course of several months to 3 to 5 years. For this reason, limited infections can be observed expectantly. More diffuse infections or infections that show continued extension can be considered for treatment. No definitive treatments are available for molluscum contagiosum.

Most treatments, similar to those used for warts, are destructive. Immune enhancement for these infections has been tried, but its utility has not been proved. Furthermore a recent commentary suggested that such interventions are of unproved utility.⁴⁶ Multiple treatments have been used, although utility is uncertain in all but curettage. A recent review suggested that resolution of disease was equivalent in groups of patients treated compared with those not treated.⁵

Parvovirus B19 Infections

See Chapter 152.

Gianotti-Crosti Syndrome (Papular Acrodermatitis of Childhood)

Gianotti-Crosti syndrome (papular acrodermatitis of childhood) is a viral exanthem first reported in 1955 by Gianotti,³⁰ who described a group of children who presented with predominantly acral located, skin-colored, or slightly erythematous lichenoid papules (Fig. 60B.2).⁸⁰ The flexures usually were spared. Involvement of the buttocks or trunk was seen in some cases. No involvement of mucous membranes occurred. Patients generally were healthy. The initial reports showed prior infection with hepatitis B. The eruption lasted 2 weeks to 2 months.

Since the initial report, similar cases have been associated with other infections, such as Epstein-Barr virus, coxsackievirus, echovirus, other viruses, and streptococcal disease.^{44,59} Most cases are thought to be viral

FIG. 60B.2 Diffusely distributed, isolated, monomorphous skin-colored papules on the thigh of a child typical of Gianotti-Crosti syndrome.

in origin and have been reported after vaccination.⁷¹ Topical therapies do not hasten resolution of the exanthem.

Asymmetric Periflexural Viral Exanthem

Some children have been described with discrete or grouped lichenoid papules or urticarial papules beginning around flexures or the torso (Fig. 60B.3).²⁹ The eruption generalizes over several days and can appear as a more diffuse case of the papular acrodermatitis of childhood.¹⁶ The condition also has been described as unilateral laterothoracic viral exanthem and seems to be associated with the same infectious agents as described in papular acrodermatitis of childhood.⁵² The evolution of this condition is similar to that in papular acrodermatitis of childhood.

Hand, Foot, and Mouth Syndrome

While typical cases of hand, foot, and mouth disease are usually easily recognized, there have been atypical cases with more diffuse skin findings described over the past several years. Some have been mistaken for infections due to HSV (Figs. 60B.4 and 60B.5).^{13,58} When occurring in patients with atopic dermatitis, more diffuse involvement can be seen and has been called “eczema coxsackium.”^{49,51} While many of these

FIG. 60B.3 Lichenoid papules involving the lateral trunk typical of the unilateral periflexural viral exanthem.

FIG. 60B.4 Inflammatory papules and plaques involving all extremities.

FIG. 60B.5 Erythematous papules, plaques, and erosions involving the buttocks and perineum.

FIG. 60B.6 Healthy adolescent who presented with eye pain and grouped vesicles/erosions on face with known diagnosis of atopic dermatitis.

“atypical” hand, foot, and mouth infections have been found to be associated with coxsackievirus A6, a recent publication was unable to make a clear clinical distinction from more “classic” viral etiologies, except when perioral involvement was seen, which was more often associated with coxsackievirus A6.⁴²

Herpes Simplex Virus

Infections due to HSV are completely reviewed elsewhere. The clinician should, however, be aware that skin infections due to HSV in patients with atopic dermatitis can be easily overlooked and often confused for secondary bacterial infections (Fig. 60B.6). Eczema herpeticum usually occurs without systemic involvement, but serious illness and death due to disseminated disease can occur. Younger patients and systemic symptoms are usually seen in patients requiring hospitalization.⁴⁸ Clinicians often question if management of atopic dermatitis in such patients

FIG. 60B.7 Nonscarring alopecia associated with tinea capitis.

can include topical antiinflammatory agents while treating the viral superinfection, but this can be continued.³

Varicella-Zoster Virus

See Chapter 162.

FUNGAL INFECTIONS

Superficial fungal infections, which include dermatophytes, yeast, or dematiaceous fungi, are encountered frequently in general pediatric practice. Particularly in an immunocompromised patient, fungal infections also may involve deeper cutaneous structures and other organ systems. This section focuses on the skin manifestations, diagnosis, and treatment of pediatric superficial fungal infections.

Superficial Fungal Infections

Dermatophyte Infections

Dermatophytes invade and grow in hair, nails, and the outer layer of the skin known as the stratum corneum. These lesions vary in appearance based on the site of infection and are named accordingly.

Tinea capitis. Also known as scalp ringworm, tinea capitis is seen frequently in prepubertal children. The causative organisms vary according to country; in North America, tinea capitis is caused largely by *Trichophyton tonsurans* and less often by *Microsporum canis*.^{20,68,82} *M. canis*, a zoophilic dermatophyte common to suburban and rural areas, can be transmitted to children who handle infected animals such as cats, dogs, and certain rodents; however, it does not spread between humans.⁶⁸ Thick, white patches of broken hair that fluoresce under Wood lamp examination characterize these lesions.

Human-to-human transmission of *T. tonsurans* occurs through the shedding of spores from infected skin scales and hair on items such as clothing, bed linen, combs, and hairbrushes. Lesions caused by *T. tonsurans* do not fluoresce under a Wood lamp and vary in appearance from diffuse scaling of the scalp to circumscribed areas of scaling and erythema with or without hair loss and, in dark-haired individuals, to scaly patches of hair loss that may leave small dark hairs in the follicles (black-dot ringworm) (Fig. 60B.7). Tinea capitis lesions may be associated with suboccipital or posterior cervical lymphadenopathy and may produce more inflammatory lesions, including scaly, pustular areas of hair loss and formation of a kerion—a boggy, erythematous mass with follicular pustules that may lead to permanent hair loss and scarring if left untreated (Fig. 60B.8).^{20,38,82} Another hypersensitivity response to the dermatophyte infection is a dermatophytid or id reaction, which involves papulovesicular inflammatory eruptions adjacent to or distant from the site of the primary infection (Fig. 60B.9).⁸

Tinea capitis must be distinguished from alopecia areata, which consists of patches of total hair loss without scalp changes, and trichotillomania, which may be associated with excoriations, varying lengths

FIG. 60B.8 Indurated tumor on the scalp typical of kerion.

FIG. 60B.9 Multiple skin-colored papules and pustules on the forehead typical of an id reaction to tinea capitis.

of broken hairs, and ill-defined patterns of hair loss. Differential diagnosis also includes traction alopecia, seborrheic dermatitis, psoriasis, and pityriasis amiantacea. In addition, inflammatory lesions of tinea capitis may be confused with bacterial pyoderma of the scalp.^{38,68,82}

Tinea corporis. Tinea corporis is a dermatophyte infection of the trunk or extremities. Lesions appear as erythematous patches or plaques with well-demarcated, annular borders that may be scaly, pustular, or vesicular.^{38,68,82} The application of potent topical corticosteroids may obscure these characteristic borders, resulting in a manifestation termed *tinea incognito*.⁶⁶ The differential diagnosis includes seborrheic, atopic, and contact dermatitides; psoriasis; and granuloma annulare.^{38,82}

Tinea faciei. Dermatophyte infections of the face in children are characterized by erythematous, scaly plaques that may be unilateral or occur in a “butterfly” distribution, mimicking cutaneous findings of systemic lupus erythematosus and other collagen vascular diseases (Fig. 60B.10). As with tinea corporis, differential diagnosis includes seborrheic, atopic, and contact dermatitides.^{38,82}

Tinea pedis. Tinea pedis, which occurs more commonly in adolescents than in prepubertal children, is a dermatophyte infection involving the feet. Findings vary and may be vesicles or erosions over the instep of the feet, fissuring between the toes with surrounding erythema and scaling, or diffuse scaling of the soles in a “moccasin-like” distribution. Differential diagnosis includes juvenile plantar dermatosis, dyshidrotic eczema, atopic dermatitis, contact dermatitis, granuloma annulare, scabies, psoriasis, and erythrasma.^{38,68,82}

Tinea cruris. Also predominantly seen in adolescents, particularly boys, tinea cruris often occurs in association with tinea pedis and is

FIG. 60B.10 Diffuse scaling plaques on the face caused by tinea faciei.

FIG. 60B.11 Annular scaling plaque on the upper inner thigh caused by tinea cruris.

transmitted through indirect or direct contact with infected skin scales or hair. Risk factors include obesity, friction, moisture, and tight clothing. The characteristic lesions are usually symmetric, well-demarcated, erythematous, scaly eruptions in the inguinal and inner thigh area with potential spread to the buttocks and perianal region. These lesions also may have a raised papular or pustular edge and often are very pruritic, leading to lichenification in chronic disease (Fig. 60B.11). The differential diagnosis includes seborrheic dermatitis, *Candida* intertrigo, flexural psoriasis, irritant dermatitis, contact dermatitis, and erythrasma.^{38,68,82}

Tinea unguium. The term *onychomycosis* refers to fungal invasion of the nail plate, which is termed *tinea unguium* when the infection is caused by dermatophytes. The lower incidence of tinea unguium in children compared with adults may be due to faster nail growth, decreased likelihood of nail trauma, and less exposure to tinea pedis, which often is seen concurrently with onychomycosis.^{41,73} Clinical findings of infection include superficial white patches on the surface of the nail plate, white spots under the nail, and yellowing and thickening of the nail plate that usually extends from the distal to the proximal end (Figs. 60B.12

FIG. 60B.12 Onychodystrophy and subungual hyperkeratosis involving the left thumb of a child with onychomycosis.

FIG. 60B.13 White superficial plaques typical of superficial white onychomycosis.

and 60B.13). The differential diagnosis includes psoriasis, lichen planus, hereditary onychodystrophy, and acquired trachyonychia, all of which may be distinguished from tinea unguium by their diffuse nail involvement as opposed to the more limited disease of a dermatophyte infection. Tinea unguium also may mimic *Candida* infection of the nails, but the latter disease differs in that it tends to spread distally from the proximal nail plate.^{4,34,38,57,61,74,81}

Diagnosis

Light microscopy examination with potassium hydroxide should show spores in infected scalp hairs of tinea capitis and branching hyphae in affected nail samples or skin scrapings from advancing margins of lesions on the body (Fig. 60B.13). Fungal culture on Sabouraud dextrose agar treated with chloramphenicol and cycloheximide provides a growth medium selective for dermatophytes and may aid in differentiating various species. Rarely biopsy may be required for definitive diagnosis.^{20,38,68,82}

Treatment

Localized lesions of tinea corporis, faciei, pedis, and cruris generally respond to a 2- to 4-week course of topical antifungals, such as clotrimazole, tolnaftate, ciclopirox olamine, amorolfine, or terbinafine.²⁰ Severe or refractory disease may require oral antifungal medications. Recurrence

of tinea pedis can be prevented by avoiding occlusive footwear and keeping the feet clean and dry.⁶⁸

Griseofulvin and terbinafine granules are the only oral antifungal medications approved by the U.S. Food and Drug Administration (FDA) for use in children. Other agents, including itraconazole and fluconazole, have been used successfully as off-label alternatives, however, despite limited data regarding their safety and efficacy in children.

Griseofulvin remains the gold standard for the treatment of tinea capitis in the United States. The approved dose of microsize griseofulvin is 11 mg/kg per day for 6 to 8 weeks; however, 20 to 25 mg/kg per day often is required to achieve an adequate response.⁷⁶ An alternative is the ultramicrosize formulation of griseofulvin at 10 to 15 mg/kg per day.³⁵ A 6-week course of terbinafine also has been shown to be as effective as griseofulvin, particularly in the treatment of tinea capitis caused by *Trichophyton* spp.^{25,27,34,77} For *Microsporum* infections, higher doses or longer duration of therapy with terbinafine may be required.^{25,27,31,34,43,47,56,72,77} Studies have shown that a regimen of fluconazole 6 mg/kg per day for 3 to 6 weeks has a cure rate comparable to that of griseofulvin.^{26,31,34,43,56,72,77} Continuous or pulse itraconazole therapy of 5 mg/kg per day has been noted to result in significant improvement and even cure in *Trichophyton* and *Microsporum* tinea capitis by 6 weeks; however, infection with *Microsporum* may require a longer duration of treatment with itraconazole compared with effective courses for *Trichophyton* infection.^{31,32,34,36,43,56,72} In addition, concomitant topical therapy with ketoconazole 2% shampoo or selenium sulfide 1% to 2.5% shampoo in affected individuals and household contacts reduces the number of viable spores and prevents the spread of infection.^{31,43,56,72}

At present no antifungal agent is approved by the FDA for treatment of onychomycosis in children, and data are limited regarding efficacy of topical and oral antifungal agents. Topical agents have poor penetration into the nail plate, usually leading to an inadequate response rate. Treating concurrent tinea pedis infections with topical therapy may help prevent recurrences of tinea unguium, however. Although griseofulvin is the drug of choice for treating other dermatophyte infections, it is not recommended for the treatment of onychomycosis because of the lengthy course (≤ 18 months), inadequate response, and high recurrence rate.

Terbinafine 3 to 6 mg/kg per day for 6 to 12 weeks, continuous or pulse itraconazole 5 mg/kg per day for 3 months, and fluconazole 3 to 6 mg/kg once a week for 12 to 26 weeks have been reported as safe, effective, and well-tolerated alternatives.^{32,39,62,77} Because of their keratinophilic and lipophilic natures, these agents accumulate in the stratum corneum and persist at high concentrations in the nails for months, allowing for shorter courses of therapy.^{36,37,39,41,77} Terbinafine may be crushed and taken with or without food. Optimal bioavailability with itraconazole capsules occurs when taken with fatty foods, whereas itraconazole solution should be taken on an empty stomach and may be associated with a higher incidence of gastrointestinal side effects than capsules. Studies regarding use of fluconazole for treatment of onychomycosis in children are limited, but successful therapy has been reported at a pulsed dose of 3 to 6 mg/kg once a week for 3 months.^{37,39,73}

Candida

The most common cause of fungal infection in healthy and immunocompromised children is *Candida*, and *C. albicans* accounts for most cases. These yeast forms have a predilection for moist, warm areas of the body such as mucosal surfaces and intertriginous regions and often colonize these areas, becoming part of the normal flora. Disease is caused by overgrowth and infiltration into the epidermis. Superficial infections may be seen in healthy individuals and individuals with predisposing risk factors, such as prematurity; low weight; diabetes mellitus; antibiotic, corticosteroid, or oral contraceptive therapy; and other immunocompromised states. These individuals also are more likely to develop systemic candidiasis.^{20,28,82}

Thrush is characterized by superficial, sometimes tender, white plaques on oral mucosa that reveal denuded, erythematous bases when scraped off (Fig. 60B.14). These manifestations must be distinguished from other oral cavity lesions, such as aphthous stomatitis, epidermolysis bullosa, herpes simplex, hairy leukoplakia, lichen planus, geographic tongue, erythema multiforme, and burns.⁸² Use of pacifiers in infants

FIG. 60B.14 White patches on buccal mucosa caused by *Candida albicans*.

FIG. 60B.15 Infant with *Candida* diaper dermatitis. Confluent and discrete erythematous papules and plaque involve the scrotum, penis, and suprapubic and inguinal area.

FIG. 60B.16 Onychodystrophy involving the thumb and index finger, with erythema and edema of the paronychia. These features are typical of *Candida paronychia*.

FIG. 60B.17 Dense crusting overlying the flank and buttocks of a neonate with *Candida* dermatitis. (From Rowen JL, Atkins JT, Levy ML, et al. Invasive fungal dermatitis in the 1000-gram neonate. *Pediatrics*. 1995;95:682–7.)

may increase the risk for development of thrush and colonization of the organism.⁷ Oropharyngeal candidiasis may spread to the esophagus in immunocompromised individuals and lead to difficulty with feeding.

Diaper candidiasis appears as beefy, erythematous plaques that involve the inguinal creases and perianal region and often are associated with satellite (or surrounding) erythematous papules, plaques, or pustules (Fig. 60B.15). These lesions may cause discomfort when the infant urinates onto affected skin. Superinfection with *Candida* should be suspected when irritant diaper dermatitis fails to improve within several days. Other lesions that may be confused with diaper candidiasis include psoriasis, Langerhans cell histiocytosis, and seborrheic dermatitis.⁸²

Thumb-sucking or other trauma near nail beds may lead to nontender, erythematous swelling at the base of the nails termed *paronychia* (Fig. 60B.16). Some cases are complicated by *Candida* infection. Differential diagnosis of these lesions includes psoriasis, bacterial infection, lichen planus, and pachyonychia congenita. *Candida* also may produce onychomycosis, but its distribution usually involves the proximal nail plate, in contrast to dermatophytosis of the nails, which more commonly affects the distal nail plate.⁸²

Adolescent girls may present with vulvovaginal candidiasis, which is characterized by thick, white discharge and white plaques on irritated, erythematous vaginal mucosa. These lesions may cause vaginal itching and dysuria.⁸²

Diagnosis of localized *Candida* infection usually is made clinically. Microscopic examination of potassium hydroxide–prepared scrapings of skin and mucosal lesions reveals pseudohyphae and elongated budding yeast forms. Positive cultures of infected material on Sabouraud dextrose agar or cornmeal agar may signify infection or benign colonization. Biopsy rarely is required for establishing a definitive diagnosis.

Treatment of localized *Candida* infection depends on good hygiene practices and maintenance of a dry environment in the susceptible area.

Localized infections usually respond well to topical antifungal therapy. Nystatin solution is the first-line agent used for thrush, but oral fluconazole or itraconazole and intravenous amphotericin B may be required to treat recurrent, refractory, or extensive disease, especially in immunocompromised children.²³ Nystatin or imidazole creams in conjunction with frequent diaper changes, barrier creams, and sometimes low-strength topical steroids are the recommended treatment for diaper candidiasis. Paronychia also is susceptible to nystatin and imidazole creams but may require oral therapy. Vulvovaginal candidiasis often can be treated successfully with topical azole medications, but oral azoles are recommended for refractory or recurrent cases. Adolescents can be treated with a single, 150-mg dose of oral fluconazole.^{23,66}

Congenital candidiasis, a rare form of infection acquired in utero as a result of *Candida* chorioamnionitis, can manifest in full-term and premature neonates within the first few days of life as a diffuse, erythematous, papular eruption that progresses to formation of vesicles and pustules and subsequently crusting and desquamation (Fig. 60B.17). Palms and soles also may be affected. Term infants with congenital candidiasis rarely develop systemic manifestations, and the infection usually resolves spontaneously or with topical antifungal agents, such as nystatin, imidazoles, or allylamines. Premature neonates with very

low birth weight are at risk for developing ecchymosis and necrosis of the skin with dissemination of the *Candida* infection, requiring treatment with systemic antifungal medication. Congenital candidiasis in these premature infants may manifest as sepsis or pneumonia without cutaneous findings as well.^{2,20,79}

Differential diagnosis of congenital candidiasis includes epidermolysis bullosa and infection with *Listeria monocytogenes*, *Staphylococcus*, herpesvirus, and syphilis.¹⁸ Early diagnosis is established by histologic examination of the placenta and umbilical cord, which shows the characteristic pseudohyphae and spores and white microabscesses.^{2,18} Microscopic examination and culture of the skin lesions can confirm the diagnosis.

Malassezia

Malassezia spp., most notably *M. furfur*, are lipophilic yeast forms that are found more readily in humid, tropical environments and are part of the normal skin flora in humans. Colonization begins in the neonatal period and increases with age.⁶ *Malassezia* is the organism thought to be responsible for neonatal cephalic pustulosis and tinea (or pityriasis) versicolor in older children, adolescents, and young adults. Invasion of the organism through indwelling catheters, particularly catheters being used for intralipid infusion in premature infants with very low birth weight also may lead to sepsis and death.^{4,70,79}

Neonatal cephalic pustulosis is a self-limited disease characterized by scattered, erythematous papules and pustules in a head-and-neck distribution (Fig. 60B.18). Follicular accentuation and comedones are not observed. Diagnosis usually is made clinically but may be confirmed by microscopic findings.^{6,20,79}

Tinea versicolor is characterized by macules with fine scales that are distributed on the upper body and neck. The macules may appear hypopigmented in dark-skinned individuals or tan or dark brown in lighter skinned individuals (Fig. 60B.19). Differential diagnosis includes vitiligo, pityriasis alba, pityriasis rosea, postinflammatory hypopigmentation, melasma, seborrheic dermatitis, contact dermatitis, and tinea corporis. Lesions of tinea versicolor are fluorescent yellow to orange under Wood lamp. Microscopic examination of potassium hydroxide-prepared scrapings of the lesions shows a “spaghetti and meatball” appearance owing to the presence of short, curved hyphae and round spores. Biopsy of the lesions, which usually is unnecessary, reveals the characteristic hyphae and spores invading the stratum corneum.

The recommended treatment is application of 2.5% selenium sulfide or ketoconazole shampoo. Other topical agents, such as ciclopirox, terbinafine solutions, sodium hypochlorite, and other azoles, also may be effective. Oral ketoconazole and itraconazole in single daily doses for 7 to 14 days or fluconazole 300 mg/week for 2 to 4 weeks have been suggested as effective treatments; however, these agents are not approved by the FDA for treating tinea versicolor in children because of their

limited safety and efficacy profiles.^{8,22,40,67} It is important to advise patients that skin discolorations may take months to resolve and that recurrences are very common and may require retreatment.^{20,38,67,79,82} *Malassezia* sepsis responds well to removal of indwelling catheters and rarely requires systemic antifungal therapy.⁷⁹

Chromoblastomycosis

Fonsecaea pedrosoi and less commonly *Cladophialophora carrionii* and *Phialophora verrucosa* are found in tropical climates and are organisms responsible for causing chromoblastomycosis, a chronic granulomatous disease affecting skin and subcutaneous tissue. Infection is acquired through traumatic inoculation into the skin. Cutaneous manifestations are described as pink papules that progressively enlarge to become tender, pruritic, hyperkeratotic nodules or verrucous plaques (Fig. 60B.20). Scratching may lead to secondary infection or result in autoinoculation of the organism to other areas of the body. Infection may lead to scarring of lymphatic vessels causing obstruction and lymphedema.^{9,24,64,69}

Differential diagnosis includes tuberculosis, sporotrichosis, blastomycosis, leishmaniasis, and squamous cell carcinomas. Potassium hydroxide smears of skin scrapings reveal characteristic dark brown, round, sclerotic bodies with horizontal or vertical septa and thick, pigmented hyphae. Sclerotic bodies also are identified easily on hematoxylin and eosin stain. In addition, biopsy of the chromoblastomycosis lesions shows granulomatous inflammation with macrophages and neutrophils and a hyperkeratotic, hyperplastic epidermis with microabscesses.^{9,24,69}

FIG. 60B.18 Pustules and papules on the face and scalp from neonatal cephalic pustulosis.

FIG. 60B.19 Well-circumscribed annular scaling plaques on the neck typical of tinea versicolor.

FIG. 60B.20 Chromoblastomycosis. The wart-like growth of epidermis and dermis is a result of traumatic implantation of the etiologic agent and subsequent autoinoculation from scratching. The agent was *Fonsecaea pedrosoi*.

Treatment of localized lesions involves surgical excision, cryotherapy, or heat therapy. Chemotherapy with 5-fluorocytosine and antifungal agents such as azoles, amphotericin B, and terbinafine has been used with some success in more widespread disease.^{9,24,78}

Tinea Nigra

Tinea nigra, caused by the organism *Hortaea werneckii*, is a superficial fungal infection seen primarily in children and adolescents.^{38,53,63} The organism is found in soil, wood, sewage, salted dried fish, and vegetation, mainly in beach environments of Central and South America, Africa, Asia, and, less frequently, in the United States and Europe. Transmission occurs by direct contact.^{53,63,65} Tinea nigra usually is characterized by an asymptomatic, well-demarcated, single brown to black macule or patch primarily on the palm but may involve other areas of the body as well (Fig. 60B.21). Lesions grow slowly and usually are nonscaly.^{38,63} Tinea nigra lesions may mimic melanoma, lentigines, junctional nevi, and the hyperpigmented patches of Addison disease.^{38,63,65} Under microscopic examination, potassium hydroxide–prepared scrapings of the lesion show yellow to light brown, branched, septate hyphae (Fig. 60B.22).^{38,65} Diagnosis is confirmed further by culture, which grows oval to spindle-shaped, moist, shiny, black colonies on Sabouraud agar.^{38,63,65}

Tinea nigra has been treated successfully with keratolytic ointments or solutions, which include salicylic acid and benzoic acid and azole

and allylamine creams. Scraping the lesion with a scalpel also can remove the discoloration.⁶⁵

Trichosporonosis

Ocular Infections

Amit Bhatt

The eye can be affected by infections and infestations manifested as primary diseases or as part of systemic processes. Some infections are vision threatening, whereas others may have important implications for a generalized disease process. Ocular findings can help narrow the differential diagnosis list in some systemic diseases, such as congenital viral infections. A helpful approach in this regard is to use an anatomic scheme that reflects the primary site of ocular involvement. This chapter proceeds systematically from anterior to posterior, from infections involving the eyelids and superficial ocular surface to those involving deeper tissue and intraocular structures, and concludes with a discussion of infections involving the orbit. Some disease sites overlap, and duplications are therefore unavoidable.

Most infectious processes involving the eye can be diagnosed accurately by following the standard medical protocol: history, examination, laboratory analysis, differential diagnosis. The three simple basic tools—a visual acuity chart, a pen light, and a direct ophthalmoscope—facilitate establishing a diagnosis in most instances. In some cases, however, special ophthalmologic testing such as a slit-lamp examination, indirect ophthalmoscopy, ocular ultrasound, Gram stain and culture, or a biopsy are required. One of the cardinal rules in ophthalmology is *always* to measure the vision as the very first examination step.

INFECTIONS OF THE EYELIDS

The eyelids are composed of connective tissue, hair follicles, sweat and sebaceous glands, smooth and striated muscles, sensory and motor nerves, and vascular elements. The skin covering the eyelids is the thinnest of the entire body. The inner surface of the eyelid is covered by the palpebral conjunctiva. Bulbar conjunctiva covers the surface of the globe. Connecting these two conjunctival parts is the conjunctival fornix, which designates the most posterior limit of the conjunctiva. Sebaceous glands (the glands of Zeis) are associated with eyelid hair follicles. Meibomian glands, located within the tarsal plates of the eyelids, are also sebaceous and drain at the posterior aspect of the lid margin.¹¹⁵

Infection of the eyelids may be generalized or focal. Involvement of the skin by an infectious agent is referred to as dermatoblepharitis. *Staphylococcus aureus* and *Staphylococcus epidermidis* are the main infectious agents. The exception is angular blepharitis, inflammation at the lateral canthus, which is often caused by *Moraxella* spp. Impetigo or erysipelas of the eyelids may be caused by *Streptococcus pyogenes*. A variety of parasitic infestations, including *Demodex folliculorum*, *Sarcoptes scabiei* (scabies), *Pediculus capitis*, and *Phthirus pubis* (the pubic louse), may involve the eyelids.¹⁶¹ Infection of the lid margin is more common in adults but may occur in children. Infections of the anterior lid margin include bacterial blepharitis, molluscum contagiosum, and parasitic diseases. Infections of the posterior lid margin include those associated with chronic meibomian gland dysfunction. Herpes simplex virus (HSV) and herpes zoster virus may involve the lid and lid margin and are discussed elsewhere in this chapter.

ANTERIOR EYELID INFECTION

Staphylococcal Blepharitis

Staphylococcal eyelid infection may be acute or chronic. Typically the chronic form of the disease manifests as erythema and crusting of the lid margins, especially on awakening. Thickening of the lid margin is a frequent manifestation. Mild chronic conjunctival infection often occurs as a spillover by local reaction to material secreted by the infecting

organism. A child with staphylococcal blepharitis may be asymptomatic or may complain of ocular discomfort or a burning, itching, or foreign body sensation. Lid hygiene measures are frequently all that is required to treat the condition, consisting of twice daily baby shampoo eyelid scrubs applied gently with a clean washcloth with attention given to the lid margin. Effective lid hygiene decreases the concentration of local bacterial flora and reduces or eliminates symptoms arising from chronic staphylococcal infection. A 2- to 4-week course of topical erythromycin, bacitracin, or azithromycin ophthalmic ointments applied twice daily to the eyelid margin may hasten resolution and reduce recurrences. Ophthalmologic ointments may cause significant temporary blurring of vision; therefore they often are used only at night before sleep. Severe or refractory cases can be effectively treated with a 5-day course of oral azithromycin.⁴⁷

Molluscum Contagiosum Infection

Molluscum contagiosum is caused by members of the family *Poxviridae*. Infection of the eyelid may be unilateral or bilateral. Infection may be transmitted by skin-to-skin contact, through fomites, or by autoinoculation. Widespread development of lesions can occur as a result of autoinoculation. Epidemics in people who live in closed communities have been reported.²¹⁶ Eyelid manifestations typically include isolated nodules with mild surrounding inflammation (Fig. 61.1). The nodules are 1 to 3 mm in diameter. Older lesions frequently become umbilicated and develop a white or waxy-appearing core. Mild conjunctival injection frequently accompanies lesions on or near the margin of the eyelid. The associated conjunctivitis occasionally can be severe and chronic. In chronic cases, corneal epithelial disease may develop.

Molluscum infection is self-limited, with most lesions resolving spontaneously within a few months. However, the infection can be recalcitrant, especially in immunocompromised patients.^{304,316} Chronic or atypical molluscum contagiosum lesions involving the eye have been reported in patients infected with human immunodeficiency virus (HIV).^{191,253} In immunocompetent patients, treatment often is advocated to prevent autoinoculation, which can prolong the course of the disease. Treatment also may provide symptomatic relief. Mechanical treatment such as cryotherapy, expression or curettage of the central core, excision, and cautery may be effective.⁵⁶ Medical treatments effective against molluscum infection remote from the eye include 1% imiquimod cream²⁷⁵ and podophyllotoxin.²⁷⁶ These agents are not recommended for the treatment of periocular lesions, however, because of the possibility of injury to the eye. A newer treatment option with some proven efficacy is the use of the oral antacid cimetidine.³¹³

Parasitic Eyelid Disease

Phthirus pubis Infestation

The crab louse *Phthirus pubis* is a tiny insect adapted to living in coarse, widely spaced hair. Infestation most commonly involves pubic, axillary, and body hair. The organism is transmitted by direct person-to-person contact and perhaps by fomites.²⁶³ Infestation of the eyelid often is a marker for sexually transmitted infections, especially in adult patients.²⁶³ For these reasons, infection in children should raise concern for potential sexual abuse. Affected patients typically have unilateral, chronic blepharoconjunctivitis; some patients may be asymptomatic. Although unmagnified ocular examination may rarely reveal signs of the disease, diagnosis is best facilitated by slit-lamp examination, which offers a magnified view of the eyelid margins and eyelashes (Fig. 61.2), revealing adult lice firmly adherent to the eyelashes as well as egg cases (nits)

FIG. 61.1 *Molluscum contagiosum* typically is manifested as an isolated nodule or nodules approximately 1 to 3 mm in diameter. Older lesions often become umbilicated and develop a white or waxy-appearing core.

FIG. 61.2 Slit-lamp photo of *Phthirus pubis* infestation demonstrating adult lice firmly adherent to the eyelashes and egg cases (i.e., nits) attached to the proximal ends of the hair shafts.

attached to the proximal ends of the hair shafts. Reddish brown flecks of louse excreta may be found at the base of the cilia, and the cilia may be broken.⁵⁴ Treatment can be simple mechanical removal of the lice and nits under magnification (slit lamp or other devices).

Medical treatment often is preferred for young children because of their inability to tolerate or permit mechanical removal. The organisms also can be smothered by the application of a bland ointment such as petrolatum jelly applied four times each day to the eyelids. Physostigmine ointment administered twice daily can be used. This agent inhibits nerve transmission in the insect and thus is directly toxic to the insect. It should be used with caution in infants and small children. If physostigmine comes into contact with the eye, it has several significant side effects, such as stimulation of accommodation, which can produce blurred distance vision that may last for several hours. Medical treatment should be continued for 2 weeks to ensure eradication of new lice that emerge from nits during the normal life cycle.⁵⁴ Lindane shampoo scrubs of the scalp, pubic hair, and body are recommended if infestation is found in these areas. Clothing and bed linen should be laundered, and family members should be examined and treated as necessary. Follow-up 4 to 6 weeks after treatment is recommended to detect reinfestation.

Demodex Infection

Demodex folliculorum and *Demodex brevis* are mites that frequently infest hair follicles in humans, including the hair follicles of the eyelids (Fig. 61.3).^{89,161} The organisms historically have been considered nonpathogenic parasites,¹⁴⁸ although it is thought they may cause increased hordeola formation as a result of obstruction of eyelid sebaceous glands.

FIG. 61.3 *Demodex folliculorum* and *Demodex brevis* are mites that can infect the hair follicles of the eyelids and are found more commonly on eyelashes with cylindrical dandruff.

Demodex is found in patients with rosacea, although a causal relationship is difficult to establish.²³⁴ Rosacea-like eruptions have been attributed to *Demodex*, and one pathologic report demonstrated a granulomatous dermal inflammation.²²² Treatment with topical pilocarpine gel may alleviate itching caused by *Demodex* infection.⁹⁹ Because of the frequency of *Demodex* infestation and the paucity of definitive disease caused by the organism, treatment often is unnecessary.

Posterior Eyelid Infection

Hordeolum

A hordeolum (i.e., sty) is an infection of the sebaceous glands in the eyelids. When the glands of Zeis are involved, the term *external hordeolum* is used. The lesion typically points to the skin surface. When the meibomian glands are involved, the term *internal hordeolum* is used. An internal hordeolum may point toward the skin or toward the palpebral conjunctiva. *S. aureus* is the most common causal agent of both internal and external hordeola.¹⁶⁵

Patients with disease of the lid margin, such as those with chronic blepharitis, seborrhea, or rosacea, are prone to recurrent hordeola, especially during the first decade of life. Hordeola are manifested by erythematous, elevated, tender nodules. Nodules typically are 5 to 10 mm in diameter and usually solitary, although they may be multiple or bilateral. Patients with a history of recurrent hordeola may have them in various stages of evolution or resolution.

The lesions usually are self-limited and typically resolve within 5 to 7 days with spontaneous drainage of the abscess. Warm compresses may hasten resolution and improve comfort. Parents should be advised to place a clean washcloth soaked in warm tap water on the involved eyelid for 10 to 15 minutes several times each day. Parents should be advised to ensure that the water is not hot enough to cause a burn. For significant coexisting blepharitis, a topical antibiotic such as erythromycin ointment may prove useful by reducing the normal bacterial skin flora of the eyelid and decreasing the risk for recurrence. Systemic antibiotics rarely are indicated for acute hordeola. Children with frequent recurrences, however, may benefit from a short course of systemic antibiotics such as azithromycin,⁴⁷ erythromycin, or tetracycline (only for children older than 12 years). These agents further decrease the bacterial flora on the eyelid and may reduce the risk for recurrence even more. Lid hygiene efforts, as described for the treatment of staphylococcal blepharitis, should be instituted and maintained for children with recurrent hordeola. Surgical drainage of a hordeolum usually is unnecessary.

Chalazion

Cytologically a chalazion may represent either a mixed-cell granulomatous inflammation or a suppurating granuloma.⁷¹ The lesion occurs in a meibomian gland as a result of a foreign body reaction to secretions produced by the gland that have been extruded into surrounding tissue. A chalazion may develop after resolution of an internal hordeolum, in

which case it is preceded by an acute stage, or it may develop primarily, without a preceding acute inflammatory phase. A typical chalazion appears as a round, nontender nodule within the substance of the eyelid. Multiple and bilateral chalazia may occur in susceptible patients. Recurrent lesions are not uncommon findings. They are typically 2 to 10 mm in diameter.²⁰⁶

Spontaneous resolution of smaller chalazia can be anticipated after a period of observation without treatment, sometimes as long as several months. Larger lesions, particularly those greater than 10 mm in diameter, frequently do not resolve without specific treatment. In patients with an acute or chronic inflammatory component, application of warm compresses may be beneficial. The majority of chalazia resolve in time, but indications for earlier surgical intervention include unacceptable cosmesis, induced visually significant astigmatism, and visually significant ptosis. In rare circumstances, chalazia can result in vision loss from amblyopia.⁷⁹ The most common surgical treatment offered is incision and curettage through an internal incision on the palpebral conjunctival surface. Surgery is highly effective. It can be performed in the office, but general anesthesia is required for most young children. Because of the need for general anesthesia, we typically recommend deferring surgical treatment until several months have elapsed without spontaneous resolution. Earlier intervention may be recommended if the chalazion is particularly large, if pigmentary changes have developed in the overlying skin, or if astigmatism or ptosis is present in a young child at risk for the development of amblyopia.

Chalazia can be treated by intralesional steroid injection, surgical incision,⁷² or both.⁹¹ Dhaliwal and Bhatia⁷² reported that incision plus curettage was the procedure of choice for lesions that have been present for 8.5 months or longer and for lesions 11.4 mm or larger in size, based on the results of a prospective study. The major potential drawback of intralesional steroid injection is the risk for complications developing with an otherwise relatively benign condition. Rarely steroid injection can result in sterile abscess formation or eyelid necrosis. Intralesional injections are done best with a chalazion clamp in place to protect the underlying globe from accidental needle trauma during injection. This device places a metal plate between the chalazion and the eye. If general anesthesia is required, incision and curettage is recommended over intralesional steroid injection.

Dacryoadenitis

Dacryoadenitis is an uncommon ophthalmic condition. Even in a busy ophthalmology practice, dacryoadenitis was diagnosed in approximately 1 in 10,000 patient visits.²³⁸ The clinical manifestation is variable. Localized tenderness and swelling of the temporal aspect of the upper eyelid usually occur and often produce an S-shaped deformity of the lid margin. Pain is frequently a predominant feature. Associated signs and symptoms include fever, follicular conjunctivitis, mucopurulent discharge, limited extraocular movement, and proptosis.²³⁸ Keratoconjunctivitis sicca has been reported as a consequence of Epstein-Barr virus (EBV)-associated dacryoadenitis in a child.¹⁸⁶

Before the era of widespread immunization, mumps was a leading cause of dacryoadenitis. Today, inflammatory etiologies predominate, including idiopathic orbital inflammation (orbital pseudotumor). Bacteria such as staphylococci, streptococci, and gonococci have been occasionally implicated. Exceedingly rare organisms such as *Brucella* are involved occasionally in bacterial cases.¹⁶ EBV has also been implicated as a causative agent in some nonsuppurative cases. Marked regional lymphadenopathy may be a distinguishing feature of EBV dacryoadenitis.²³⁸ Other rare infectious causes include tuberculosis and Lyme disease.^{207,248,251}

Appropriate laboratory evaluation includes Gram stain and culture of any mucopurulent discharge from the eye. Neuroimaging is indicated when the patient has severe inflammation, proptosis, limitation of extraocular movement, or other orbital signs to rule out a more generalized orbital process. The condition easily can be confused clinically with orbital cellulitis when signs and symptoms are severe. Biopsy of the lacrimal gland may be required to confirm the diagnosis in patients not responding to standard medical treatment or when atypical features are identified on clinical examination or radiographic studies. Blood cultures are indicated for patients with signs of systemic toxicity.

Intravenous nafcillin or vancomycin is a reasonable initial antibiotic choice for severe dacryoadenitis caused by gram-positive organisms. Oral antistaphylococcal agents may be used for less severe cases. For gram-negative cases, ceftazidime or other similar agents should be considered. For suppurative cases without Gram-stain guidance, intravenous nafcillin or vancomycin should be considered as initial therapy for severe cases and oral antistaphylococcal agents for less acute cases.

Therapy in the form of warm compresses and oral analgesics is indicated for nonsuppurative dacryoadenitis. Serum testing for evidence of EBV infection should be considered in patients with regional lymphadenopathy.²³⁸ Other noninfectious causes of dacryoadenitis include sarcoidosis, Sjögren syndrome, leukemia, lymphoma, eosinophilic granuloma, autoimmune vasculitis (Churg-Strauss syndrome and Wegener granulomatosis), and immunoglobulin (Ig) G4-related systemic disease.^{46,144,153} Noninfectious cases of dacryoadenitis sometimes can be difficult to distinguish from infectious cases. Lacrimal gland biopsy and neuroimaging usually are necessary to establish a diagnosis in noninfectious cases.¹⁷² Steroid treatment has been shown to be effective in the management of acute idiopathic dacryoadenitis; it results in marked improvement of symptoms within 24 to 48 hours in most cases.¹⁹⁴

Nasolacrimal Duct Obstruction

Simple membranous nasolacrimal duct obstruction occurs in an estimated 1% to 20% of the newborn population, and intermittent, mild, self-limited bacterial infection is a commonly associated feature.^{93,113,171,209} It most commonly results from a blockage of the valve of Hasner, which is the opening from the lacrimal sac into the inferior nasal meatus. The signs of nasolacrimal duct obstruction consist of an increased tear lake, mucopurulent discharge, and epiphora. The periocular skin is sometimes mildly erythematous, with skin fissures in regions of pronounced irritation. The conjunctiva and sclera are usually white and are uninvolved. When pressure is applied over the lacrimal sac there is a reflux of mucopurulent material from the punctum.

More than 50% of congenital nasolacrimal duct obstructions resolve without surgical intervention.^{205,220,224,228} Most cases can be observed with treatment limited to gentle lid hygiene and lacrimal sac massages. In more severe cases, medical treatment with a topical antibiotic is appropriate. The most common organisms identified in nasolacrimal duct obstruction cultures include *Streptococcus pneumoniae* and *Haemophilus influenzae*.²⁹³ Most ophthalmologists prefer topical fluoroquinolones over aminoglycosides because they cause less ocular irritation and have better coverage of gram-positive organisms. When the condition fails to resolve, a probing procedure can be performed in the nasolacrimal duct system, which typically is successful in resolving the condition. This procedure is commonly performed in the operating room under general anesthesia but also can be performed in an office setting with restraint when performed in children younger than 1 year.

Dacryocystitis

Dacryocystitis may result from congenital or acquired lacrimal outflow obstruction. This condition is manifested as acute erythema, pain, and swelling in the medial canthal region. The swelling typically is located below the medial canthal tendon. Marked epiphora generally is present, and a mucopurulent discharge frequently can be expressed through the lacrimal punctum if the proximal aspect of the lacrimal drainage system is not obstructed. If the infection has resulted in or from obstruction proximal and distal to the lacrimal sac, the overlying skin may become tense as the nasolacrimal sac distends in response to the infectious process. Formation of a fistula to the overlying skin may occur as a result of dacryocystitis, and surgical excision of the fistula tract often is needed after the acute process has resolved. Dacryocystitis is a particularly common finding in neonates with a dacryocele, with dacryocystitis developing in as many as 60% of affected neonates.²²¹

Aerobic and anaerobic bacteria and fungi may produce dacryocystitis.^{34,35} In one study, *S. epidermidis* and *Pseudomonas* spp. were the aerobic organisms identified most frequently, and *Peptostreptococcus* spp. and *Propionibacterium* spp. were the anaerobes isolated most frequently. Less common agents include *Escherichia coli*, *Pseudomonas* spp., *H. influenzae*, *Pasteurella multocida*, and various anaerobes. Laboratory investigation should include aerobic and anaerobic culture of

mucopurulent discharge from the lacrimal sac. Frequent massage of the lacrimal sac may be used to facilitate expression of material for Gram stain and culture and to aid in resolution. A sepsis workup should be considered for children who are acutely ill and for young infants.

Intravenous nafcillin, vancomycin, or both are good initial therapeutic choices for serious gram-positive infections. Mild cases in older children can be treated with oral antibiotics. Intravenous ceftazidime is a reasonable initial antibiotic choice for gram-negative dacryocystitis. Intravenous nafcillin or vancomycin typically provides good initial empiric therapy in patients when Gram-stain guidance is not available.

Ophthalmologic consultation should be requested in all cases of acute dacryocystitis. Decompression of the lacrimal sac by aspiration, incision, and drainage or probing the proximal lacrimal drainage system may be needed to hasten resolution. Probing of the distal lacrimal system often is deferred until the acute infection has subsided, as complications from probing can lead to postseptal spread and subsequent orbital cellulitis. Mucopurulent material obtained during surgical decompression should be sent for appropriate culture.

Preseptal (Periorbital) Cellulitis

The term *preseptal cellulitis* refers to an infectious process in the eyelids that is isolated to regions anterior to the orbital septum. The orbital septum is a thin layer of fascia that extends vertically from the periosteum of the orbital rim to the tarsal plate within the eyelids. Although it is penetrated by nerves and vascular structures, the septum provides a barrier that slows the spread of infectious agents into deeper orbital and retroorbital structures.²⁷¹ Typical signs and symptoms of preseptal cellulitis include erythema and edema of the eyelids. Distinctively absent are signs of deeper orbital involvement such as restricted ocular motility, pain with eye movement, and proptosis. Preseptal cellulitis may occur after trauma or be caused by spread of infection from adjacent structures, such as skin and the upper respiratory system.³⁰²

Posttraumatic Preseptal Cellulitis

Posttraumatic preseptal cellulitis occurs after puncture wounds on the lids, face, or scalp. It also may occur after blunt trauma with no obvious entry wound. The etiologic agents most commonly identified are *S. aureus* and *S. pyogenes*, and polymicrobial infections can occur. Other bacterial causes include non-spore-forming anaerobes such as *Peptococcus*, *Peptostreptococcus*, and *Bacteroides*. Infection by aerobic gram-negative bacilli is an uncommon finding.¹³ *P. multocida* is a common organism that produces posttraumatic preseptal cellulitis after dog and cat bites.^{160,164} Cellulitis secondary to methicillin-resistant *S. aureus* (MRSA) is increasing in frequency and is a common cause of community-acquired cellulitis in some locations.

Clinical signs and symptoms are determined in large part by the severity of the injury, the interval since injury, and the infecting organisms. The involved lids are edematous, erythematous, and typically quite tender. Fluctuation of subcutaneous tissue may be present if an abscess has developed. Swelling of the uninvolved contralateral eyelids may occur as a result of lymphedema. As with any form of isolated preseptal cellulitis, vision is unaffected, and proptosis and eye movement disturbances are absent. On rare occasions, eyelid edema may be sufficiently severe to preclude adequate evaluation of the eye. Neuroimaging is required in such cases to assess the globe and rule out involvement of structures posterior to the orbital septum. Ophthalmologic consultation is critical in cases of severe posttraumatic preseptal cellulitis because of the potential for concurrent globe injury.

Laboratory analysis includes Gram stain and aerobic and anaerobic culture of any mucopurulent material to aid in therapeutic decisions. Amoxicillin-clavulanate or a related agent is the drug of choice for treating posttraumatic cellulitis caused by a dog bite because of the high prevalence of *P. multocida*. Tetanus prophylaxis should be guided by standard recommendations. Surgical drainage of large abscesses may be required if a rapid response to antimicrobial therapy does not occur.

Nontraumatic Preseptal Cellulitis

The clinical features of nonsuppurative, nontraumatic preseptal cellulitis depend to a large degree on the causative agent. Erythema and swelling of the involved eyelids are typical and are often accompanied by pain.

Signs of orbital infection such as altered vision, proptosis, and eye movement abnormalities are absent.

Before the advent of *H. influenzae* type b vaccine, this organism frequently was a cause of nonsuppurative preseptal cellulitis in children. It was a particularly dangerous agent because of a high risk for spread to the central nervous system (CNS), which occurred in as many as 2% to 3% of patients. Although rare today, *H. influenzae* type b infections still may be encountered. Like many infecting organisms, it gains access to subcutaneous tissue through infected nasal passages.

S. pneumoniae is now the most common bacterial cause of preseptal cellulitis in the pediatric age group.⁷⁸ It occurs in association with upper respiratory tract infection, although constitutional symptoms usually are less pronounced than those associated with *H. influenzae* type b infection. A variety of other bacterial agents may cause preseptal cellulitis, but they are seen less commonly. Preseptal cellulitis occasionally has been reported to be due to a variety of other organisms, including *Trichophyton* (ringworm),²⁹⁶ tuberculosis,²³¹ and anthrax.⁹⁴¹

Adenovirus is another particularly common cause of preseptal cellulitis in children. Adenovirus is an important consideration in the differential diagnosis of childhood preseptal cellulitis because, despite being self-limited, the condition can occasionally mimic bacterial infection and prompt unnecessary treatment with antibiotics. Adenovirus can be recognized by its characteristic copious discharge, which may be serous. Swelling of the lid may be prominent, but erythema usually is minimal. Preauricular lymphadenopathy often occurs in older children, and marked conjunctival hyperemia with or without chemosis and subconjunctival hemorrhage may be present. Photophobia may also be observed in cases of concurrent punctate keratopathy. A history of recent contact with other infected individuals frequently is noted and should be sought. Care should be taken to avoid spreading infection to family members, medical personnel, and others.

Hospital admission should be considered for children younger than 1 year of age with bacterial preseptal cellulitis. Hospitalization also is important for children with signs of systemic toxicity and those with inadequate *H. influenzae* immunization. A sepsis workup is indicated for children with signs of systemic toxicity and for extremely young children. Ophthalmologic consultation is recommended if orbital involvement is suspected or if clinical examination is inconclusive. Computed tomography (CT) usually is unnecessary for isolated preseptal cellulitis. Cultures of blood obtained from patients with preseptal cellulitis generally are negative but are more likely to be positive in children younger than 2 years. Culture of conjunctival discharge is done often but rarely has significant diagnostic benefit. A severity index for scoring preseptal cellulitis in children has been reported to help guide treatment decisions.²⁹⁹

Antibacterial treatment should include intravenous agents for infants and those with signs of serious systemic infection. Intravenous cefuroxime or a combination of nafcillin plus cefotaxime or ceftriaxone frequently is recommended for empiric therapy. When MRSA preseptal cellulitis is suspected because of poor response to treatment or through cultures, clindamycin and trimethoprim-sulfamethoxazole are often the first-line agents. In situations in which MRSA preseptal cellulitis does not respond favorably to these medications, vancomycin or linezolid with rifampin may be effective treatments.^{11,270} Outpatient treatment with intramuscular or oral antibiotics is reasonable for older, less acutely ill children. Systemic antibiotics should be continued for 7 to 10 days. Patients in whom intravenous antibiotics are started initially can switch to an oral antibiotic after they have been afebrile for at least 24 hours and otherwise have improved clinically, unless the possibility of development of sepsis remains a concern. When antibiotic treatment fails, other noninfectious causes should be explored.

Orbital Cellulitis

Orbital cellulitis refers to infection of orbital structures posterior to the orbital septum and is the most frequent cause of acute orbital inflammation. Orbital cellulitis occurs more commonly in children and more frequently during cold weather, when sinusitis is more prevalent.

Initial signs and symptoms can vary from mild inflammation to severe and fulminant orbital disease. Cardinal signs and symptoms of

infectious orbital cellulitis include proptosis, limited eye movement (including total ophthalmoplegia), pain with eye movement, and an abnormal pupillary response. Decreased vision or even blindness can occur as the most serious ophthalmic complication.²⁴⁷ Death can result from intracranial extension of the infection if appropriate treatment is not initiated. Elevated intraocular pressure and chemosis of the conjunctiva are common ancillary signs. Preseptal cellulitis often coexists with orbital cellulitis but is not a prerequisite.

Most cases of orbital cellulitis are caused by spread of infection from an adjacent infected sinus.^{49,200} Ethmoid sinusitis is the most common predisposing factor.¹⁹² Rare cases are due to penetrating orbital trauma or skin infection involving the face, with spread of organisms into the orbit. Orbital cellulitis may occur infrequently after orbital, ocular, or periocular surgery.^{7,218,310} Orbital cellulitis and cavernous sinus thrombosis have been reported to occur after dental infections and dental surgery.³⁸

Comprehensive evaluation of a patient with confirmed or suspected orbital cellulitis includes ophthalmologic and systemic examination. Assessment of visual acuity individually in each eye is important for excluding vision loss and establishing a baseline to aid in monitoring progression of the disease or the effects of therapy. Evaluation of optic nerve dysfunction by examining the pupils for an afferent pupillary defect (APD) is of utmost importance throughout the course of the disease. Careful evaluation of extraocular movement should be performed in all extreme positions of gaze to identify limitation of ocular duction and to evaluate for pain on eye movement. The presence or absence of proptosis can be assessed clinically by viewing the eyes from above (bird's-eye view) or below (worm's-eye view) and by comparing their relative positions within the orbits. In severe cases of orbital cellulitis, funduscopic examination may reveal dilation of the retinal venules and signs of compressive optic neuropathy, such as optic disc edema. In severe cases, central retinal artery and vein occlusions have been reported.^{60,139,214} Systemic evaluation includes determination of temperature, which usually is in the range of 39°C to 40°C (102°F to 104°F). Sinus examination, a screening neurologic examination, and evaluation for signs and symptoms of sepsis and meningitis should be performed.

In any case of clinically definite or suspected orbital cellulitis, CT of the orbit and brain is essential. CT can establish or confirm the diagnosis of orbital cellulitis and provides critical information needed to manage the patient. Imaging of the brain is important because orbital cellulitis can evolve into a brain abscess, meningitis, or cavernous sinus thrombosis. However, when a clinical response to treatment is noted, improvement in CT findings frequently is delayed. Therefore recurrent CT scanning of a child with clinically improving findings is not indicated unless new signs or symptoms of concern develop.

Microbiologic studies often are acutely unhelpful for the routine patient with orbital cellulitis. Nonetheless baseline studies remain important because critical information sometimes is acquired. Blood culture samples should be obtained at a minimum, and a lumbar puncture with culture of cerebrospinal fluid (CSF) should be considered in infants and those with signs of CNS infection. Culture of the ocular, nasal, and nasopharyngeal mucous membranes is of limited value and can be omitted. However, if surgical drainage is performed, samples of any material removed should be obtained for culture.

Optimal management of a child with orbital cellulitis requires a multidisciplinary approach. In addition to evaluation and management by an experienced pediatrician, ophthalmologic and otolaryngologic consultation should be obtained. Neurosurgical consultation is required when involvement of the CNS is diagnosed or suspected. In atypical cases and those not responding to treatment, consultation with an infectious disease specialist is warranted.

The most common offending etiologic bacteria are *S. aureus*, *Streptococcus* spp., and *Haemophilus* spp. (other than *H. influenzae*).¹⁸⁵ *S. pneumoniae* also is implicated frequently, and a variety of less common organisms have been reported. *H. influenzae* orbital cellulitis rarely has occurred since widespread use of the *H. influenzae* type b vaccine was implemented.^{3,78} Fungal infection of the orbit occasionally is encountered, typically in immunocompromised individuals.¹⁸³

The differential diagnosis of orbital inflammation in children includes a broad range of noninfectious conditions, including blunt trauma,

idiopathic orbital inflammation (orbital pseudotumor), Wegener granulomatosis, sarcoidosis, leukemic infiltration, lymphoma, rhabdomyosarcoma, necrotic retinoblastoma, metastatic carcinoma, and histiocytosis X. Thyroid ophthalmopathy also can be manifested as an acute orbital inflammatory process, although usually its onset is slow and insidious.

Treatment of all patients with orbital cellulitis requires hospitalization and initiation of intravenous antibiotics as soon as possible. Infection with penicillin-resistant organisms is an increasingly common occurrence and must be considered during treatment.^{44,265} Appropriate initial antibiotic therapy may include nafcillin, metronidazole, and cefotaxime as combination therapy. Given the increasing incidence of MRSA, initial treatment with vancomycin or clindamycin should be considered.^{53,245,256} Other antimicrobial agents may be useful, and local susceptibility patterns should guide the choice of initial antimicrobial therapy. Antibiotic coverage should be modified according to the clinical course and culture results. If the patient fails to respond to antibiotic treatment within 24 to 48 hours, consultation with an infectious disease specialist and repeat CT to look for the development of an orbital abscess should be considered (Fig. 61.4). The mean hospital stay for uncomplicated cases of orbital cellulitis is 10 to 14 days, and oral antibiotics should be prescribed for 7 to 10 days after discharge. When the source of infection is believed to be from sinusitis, a nasal decongestant is commonly prescribed to aid in opening the sinus ostia, promoting drainage of the infected sinus, and speeding resolution. Nasal decongestants should be continued for 7 to 10 days after initiation.

Although treatment of orbital cellulitis with steroids remains controversial, their use in the treatment of acute and chronic sinusitis has become increasingly common. Studies have shown that steroids can reduce levels of inflammatory cytokines in the sinonasal mucosa of individuals with sinusitis.^{40,301} In a study on the use of steroids in children with orbital cellulitis, Yen and Yen³¹⁴ reported no adverse effects of this adjunct treatment with systemic antibiotics. Prospective studies on the use of steroids in orbital cellulitis have been proposed to determine whether they have any clinical benefit.

Children with orbital cellulitis require diligent follow-up while in the hospital. Vision should be assessed at the bedside daily; results may be more accurate if a single examiner routinely assesses vision for a given patient. Pupillary examination for an APD should be performed at each examination. Development of an APD indicates compromise

FIG. 61.4 Failure of response of orbital cellulitis to antibiotic treatment may be a sign of development of a subperiosteal orbital abscess (seen here in the right medial orbit).

BOX 61.1 Indications for Consideration of Surgical Drainage in Orbital Cellulitis

1. Age ≥ 9 years
2. Presence of frontal sinusitis
3. Nonmedial location of orbital abscess
4. Large orbital abscess ($\geq 1250 \text{ mm}^3$)²⁸⁹
5. Suspicion of anaerobic orbital infection
 - a. Presence of gas within the abscess space
 - b. Infection of dental origin
6. Recurrence or abscess after prior drainage
7. Evidence of chronic sinusitis (e.g., presence of nasal polyps)
8. Acute optic nerve or retinal compromise

From Garcia GH, Harris GJ. Criteria for nonsurgical management of subperiosteal abscess of the orbit: analysis and outcomes 1988–1998. *Ophthalmology*. 2000;107(8):1454–6.

of the optic nerve, warrants escalation of treatment, and usually requires urgent surgical intervention. Worsening of extraocular motility, altered mental status, or onset of CNS signs raises the concern of progression to cavernous sinus thrombosis and should prompt emergency repeat neuroimaging of the brain and orbit, with further intervention as dictated by results of the scan. The close anatomic relationship of the orbit to the brain, with the orbital venous system freely anastomosing with the facial venous plexus and cranial venous sinus system through a series of valveless veins, seriously increases the potential for spread of infection to contiguous structures, including the brain.

Acute surgical intervention to decompress the orbit or drain an orbital or subperiosteal abscess is indicated if vision loss or an APD is identified at any point during treatment. Helpful drainage criteria have been described (Box 61.1). Immediate neurosurgical consideration is indicated if CNS involvement is documented. Most patients without evidence of vision loss, optic nerve dysfunction, or CNS involvement can be managed successfully medically.^{111,244} Provided that clinical improvement continues, no worrisome signs or symptoms of CNS involvement develop, and the patient's overall clinical status does not worsen, repeat neuroimaging of patients with an orbital abscess is unnecessary. Short-term resolution of an orbital abscess often is not obvious on CT. The radiographic appearance of the abscess typically remains unchanged on early follow-up scans, although it may no longer contain viable organisms.

Sinus drainage by an otolaryngologist frequently is required to hasten resolution. Formation of an abscess is not a prerequisite for surgical intervention, and orbital cellulitis without abscess formation may progress to the point of requiring surgery. Despite prompt and appropriate treatment, serious complications such as permanent vision loss and brain abscess can occur.^{36,66,122,237,247} Most patients, however, can be treated effectively with no permanent sequelae.

Orbital cellulitis caused by fungal infection has a course and prognosis markedly different from those of bacterial orbital cellulitis, particularly cellulitis caused by mucormycosis and aspergillosis. Fungal orbital cellulitis typically occurs in patients who are immunocompromised or patients with metabolic acidosis, such as those with poorly controlled diabetes. It may be manifested as a subacute or chronic process. Orbital apex syndrome is considered to be the most severe form, with loss of function of all cranial nerves traversing the orbital apex into the orbit (i.e., cranial nerves II, III, IV, V, and VI). A black eschar-like lesion may form in the oropharynx or nasopharynx in cases of fungal infection.

Aspergillus orbital infections (most commonly caused by *Aspergillus flavus*, *Aspergillus fumigatus*, or *Aspergillus oryzae*) are rare findings in children and may take a slow, chronic course over a period of months or years. No clear predisposing factors exist, but it has a predilection for humid climates, and most cases occur in otherwise healthy individuals. Signs and symptoms of orbital infection caused by *Aspergillus* spp. include loss of vision, constant dull pain, decreased or absent ocular motility, and proptosis with firm resistance to retropulsion. Palate and nasopharyngeal lesions occur but are rare. Biopsy is required for establishing the diagnosis.¹¹⁰

Effective treatment of orbital fungal infection requires correction of systemic and metabolic disturbances and administration of intravenous antifungal agents such as amphotericin B. Posaconazole has been shown to be effective as an alternative treatment in those who fail to respond to or cannot tolerate treatment with amphotericin B.²⁴⁶ Surgical debridement of the orbit or adjacent infected sinuses frequently is required. Treatment often is unsuccessful, and fatalities are not uncommon, particularly with mucormycosis.

The larva of *Echinococcus granulosus* can produce a hydatid cyst in the orbit. The dog is the definitive host animal, although the organism also may live in the intestines of sheep, goats, cattle, pigs, and other animals. The disease is endemic in the Middle East, Africa, and Asia. Humans become infected by eating contaminated food, typically meat, and infection may occur in any age group. Affected patients have noninflammatory proptosis, decreased ocular motility, and dull orbital pain. Surgical excision is required for treatment. The cyst may be injected with hypertonic saline to kill the parasite, followed by excision.¹⁰⁸

CONJUNCTIVAL INFECTIONS

The conjunctiva is the highly modified and specialized mucous membrane covering the inner surfaces of the eyelids and the anterior surface of the globe. The part that lines the inner surface of the eyelids is the *palpebral conjunctiva*, and the part covering the globe is the *bulbar conjunctiva*. The conjunctiva contains numerous small glands that produce two of the three parts of the tear film—a lower mucous layer acting as a wetting agent and a middle aqueous layer that makes up the bulk of the tear film; the third layer is oily and is produced by the sebaceous and meibomian glands of the eyelid and prevents rapid evaporation. The conjunctiva can be infected by many bacteria and viruses and by noninfectious allergic and toxic agents.

Conjunctivitis can cause mild or significant symptoms—burning, itching, or a foreign body sensation. Itching commonly signifies an allergic or viral cause. The conjunctival redness (injection and erythema) of infectious conjunctivitis is usually more severe when located away from the edge of the cornea, whereas conjunctival injection concentrated adjacent to the cornea (limbal or ciliary flush) suggests inflammation of the cornea (keratitis), inflammation of the iris (iritis), inflammation of the iris and ciliary body (iridocyclitis), or occasionally glaucoma or a corneal foreign body. When the eye is very severely infected, however, it may be so intensely red that such a differentiating pattern is not discernible.

Conjunctivitis is often accompanied by a discharge with important diagnostic properties. Thick purulence suggests a bacterial cause, a mucoid discharge suggests a viral infection, and a serous discharge may be seen with viral or allergic causes. Patients with isolated conjunctivitis usually do not have significant blurring of the vision. Apparent conjunctivitis with poor vision warrants a search for another diagnosis.^{104,182}

Bacterial Conjunctivitis

Mild bacterial conjunctivitis is the most common form of infectious conjunctivitis in children. It is characterized by a purulent discharge and can be unilateral or bilateral. It is useful clinically to divide bacterial conjunctivitis into mild and severe forms because the treatments are different.^{107,132}

Mild Bacterial Conjunctivitis

The agents most commonly causing mild bacterial conjunctivitis in children 5 years of age or older are *S. pneumoniae* and *Moraxella* spp.¹⁰⁴ *H. influenzae* was a prominent causative agent before the availability of *H. influenzae* type b vaccine. *S. aureus* conjunctivitis is seen most frequently after trauma or surgical manipulation. Conjunctival stains and cultures are usually not necessary, because the disease is almost invariably self-limited or responds rapidly to topical antibiotics.

Many topical antimicrobial agents for bacterial conjunctivitis are readily available and include ciprofloxacin, erythromycin, moxifloxacin, gatifloxacin, ofloxacin, norfloxacin, tobramycin, gentamicin, sulfacetamide, and various combinations. Aminoglycoside-containing compounds such as neomycin can occasionally cause a dramatic allergic blepharoconjunctivitis that is worse than the original disease. The choice of

using either drops or ointment is best left to the person who will be instilling the medication, because neither has any proven therapeutic advantage. Newer agents, such as the fourth-generation fluoroquinolones (moxifloxacin and gatifloxacin), should not be used for routine mild bacterial conjunctivitis so as to limit antibiotic resistance. A typical regimen for treatment of mild conjunctivitis is 1 drop or a ¼-inch bead of ointment placed into the inferior conjunctival fornix three to six times daily for 5 to 7 days, depending on the medication. Persistent infection calls for a prompt return to the physician for reconsideration of the diagnosis. Mild bacterial conjunctivitis generally resolves spontaneously in 7 to 14 days even without treatment.^{103,107}

Severe Bacterial Conjunctivitis

Severe bacterial conjunctivitis, characterized by ocular discomfort, pronounced redness, and copious purulent discharge, is usually caused by *Neisseria gonorrhoeae*, *Neisseria meningitidis*, *S. aureus*, *S. pneumoniae*, and, in children younger than 5 years, *H. influenzae*. A hyperpurulent state in which the copious purulent discharge reaccumulates in a matter of minutes is characteristic of infection with *N. gonorrhoeae*.^{121,266} Severe conjunctivitis calls for stains and cultures. Samples from both eyes should be stained and cultured separately, even if only one eye is involved, to allow the uninvolved eye to serve as a control.²⁷⁸ Gram stains of conjunctival scrapings should be done at the time of culture. A useful culture technique includes the use of a cotton or calcium alginate swab gently rubbed against the palpebral conjunctiva of the lower lid and inoculated onto blood and chocolate agar. If *N. gonorrhoeae* is suspected, a culture for chlamydia is also indicated, because concurrent infection with both organisms is common.^{258,261}

The treatment of severe bacterial conjunctivitis is based initially on the results of the stains and later modified according to cultures and sensitivities. If *Neisseria* is strongly suspected, the patient should be treated for *Neisseria*, even if the laboratory results are not confirmatory. Ocular *N. gonorrhoeae* infection is a vision-threatening and life-threatening disease. This organism can penetrate the intact cornea and cause microbial keratitis (i.e., infection of the cornea), corneal perforation, and endophthalmitis (i.e., infection inside the eyeball), in addition to the conjunctivitis. *N. gonorrhoeae* conjunctivitis should be considered in three patient groups: neonates after passage through an infected birth canal, sexually active individuals, and victims of possible sexual abuse. For this reason, a high index of suspicion should be maintained. Pediatric infection with *N. gonorrhoeae* requires hospital admission and administration of a systemic antibiotic. Because of the prevalence of penicillin-resistant strains, a broad-spectrum (third-generation) cephalosporin, such as ceftriaxone, is the most appropriate choice of antibiotic.¹¹⁷ Adjunctive treatment of *N. gonorrhoeae* conjunctivitis with topical moxifloxacin and simple saline irrigation for 5 days can be helpful, but topical agents should never be used as isolated treatment.¹²¹ Moxifloxacin is a particularly good antibiotic choice because it is effective against chlamydia as well.

Conjunctivitis caused by gram-positive cocci can be treated with topical moxifloxacin, gatifloxacin, ciprofloxacin, or erythromycin. Systemic nafcillin, a second- or third-generation cephalosporin, or both can be added as needed for more extensive infections. Gram-negative bacterial conjunctivitis can be treated with topical erythromycin ointment or an aminoglycoside drip such as gentamicin or tobramycin. Systemic antibiotics can be added if needed.²⁷⁸

Viral Conjunctivitis

Adenoviral Conjunctivitis

Viruses are another common cause of infectious conjunctivitis in children. Many pediatric cases of viral conjunctivitis are caused by adenovirus. Serotypes 1, 2, 3, 4, 7, and 10 produce an acute form of conjunctivitis with prominent conjunctival follicles. Serotypes 3 and 7 also may cause pharyngoconjunctival fever. This entity is characterized by conjunctivitis, fever, and pharyngitis.²⁵ Serotypes 8, 19, and 37 can cause epidemic keratoconjunctivitis (EKC).²⁷⁸ EKC is characterized by a combination of a punctate epithelial keratitis (best viewed by slit-lamp examination) and an immune response that results in subepithelial (i.e., in the corneal stroma) infiltrates. There is commonly a robust inflammatory response causing the formation of membranes on the palpebral conjunctival

surface, and there can be extensive subconjunctival hemorrhages and preseptal cellulitis. Photophobia is a prominent feature of this condition, and visual acuity may be markedly decreased. Epidemic keratoconjunctivitis is often associated with pharyngitis and rhinitis, which may precede or be concurrent with the conjunctivitis.

Adenoviral conjunctivitis may be highly contagious. It is transmitted easily from an infected individual to others at home or at school. The incubation period is 5 to 10 days but may be as long as 21 days. The virus is shed from the infected conjunctiva for 7 to 12 days after the onset of infection. Frequently, a prodromal upper respiratory tract infection consisting of fever, pharyngitis, or otitis media occurs.²⁷⁸ Ocular signs and symptoms include photophobia (with corneal involvement), foreign body sensation, epiphora (tearing), bulbar and palpebral conjunctival injection and chemosis (edema of the conjunctiva), and subconjunctival hemorrhage.¹²⁵ Preauricular lymphadenopathy is a common feature in older children and adults.

The diagnosis of adenoviral conjunctivitis is almost always clinical only. Only rarely is laboratory confirmation necessary. Viral cultures are possible when indicated, and a rapid enzyme immunoassay test is available.³⁰⁶ Treatment of adenoviral conjunctivitis is supportive, aimed at decreasing the symptoms of irritation, photophobia, and blurred vision. Cool compresses and acetaminophen are helpful. For the more aggressive EKC, topical steroids are indicated to quiet the severe immune response. Removal of conjunctival membranes with a moistened cotton swab may relieve the foreign-body sensation. A small amount of bleeding often occurs after removal of the membranes, and they can recur after several days. The use of topical steroid preparations requires careful monitoring,^{181,278} and they should only be prescribed by an ophthalmologist.^{147,262}

The clinician should wear gloves when examining patients with suspected adenovirus infection. Careful hand-washing is essential after direct contact. Instruments or equipment used in examining an infected patient should be cleaned with 10% sodium hypochlorite solution or other solutions known to eradicate the adenovirus.

Mini-epidemics of adenovirus-related conjunctivitis can originate in physicians' offices.^{13,100} At home, families should exercise caution and separate the towels and bedclothes of the patient from those of others in the household. Children of school age should be kept at home for 7 days or longer to reduce the risk for transmitting the infection to classmates.²⁷⁸

Herpes Simplex Virus Conjunctivitis and Complex Forms

HSV conjunctivitis may occur as a primary or secondary infection. Ocular infection usually is caused by HSV-1, except in newborns, in whom HSV-2 predominates.⁵¹ Typical initial signs of HSV conjunctivitis include a serous discharge, scant conjunctival follicle formation on the inferior palpebral conjunctiva, and preauricular lymphadenopathy.³¹⁷ Eighty percent of cases are unilateral. Eyelid vesicles often occur in primary infections. Bulbar conjunctival ulceration is an unusual occurrence, but when present, it is virtually pathognomonic of primary HSV-1 infection. Keratitis occurs in as many as 50% of primary cases and is characterized by mild epithelial irregularities. Dendrites (branch-shaped lesions of the corneal epithelium) can occur in primary infections, but reactivated HSV keratitis frequently exhibits the characteristic dendritic pattern. Lid vesicles usually do not develop in cases of reactivated HSV infection.¹⁴⁶

Primary HSV dermatopharitis is seen most commonly in children younger than 6 years, but it may occur at any age. The initial episode may be associated with an upper respiratory tract infection, and recurrences are common. Clinical signs include eyelid vesicular reaction, mild follicular conjunctivitis, preauricular lymphadenopathy, and, occasionally, atypical epithelial keratitis. Secondary bacterial infection can occur. Systemic acyclovir is a safe and effective treatment, although the disease itself typically is self-limited and does not require treatment.¹⁴⁶

The diagnosis of HSV keratoconjunctivitis usually is made on the basis of the clinical appearance alone. Antigen detection tests or viral cultures can be used when the diagnosis is in question.¹⁴¹ Viral cultures, when necessary, require special handling.²⁷⁸ In culturing primary HSV cases, the skin surface is swabbed with an alcohol sponge, and a tuberculin

syringe with a 30-gauge needle is used to aspirate fluid from an intact vesicle. If no vesicles are present, a Dacron swab is wiped on the palpebral conjunctiva of the lower lid. The viral transport medium is inoculated and taken to the laboratory for special handling.

Treatment of HSV conjunctivitis alone (in the absence of corneal epithelial disease) is controversial. Oral acyclovir may be used for severe cases of primary HSV infection.^{254,274} Two topical antiviral agents are available: trifluridine solution and ganciclovir ointment.

When epithelial HSV keratitis is reactivated and the typical dendritic (branched) epithelial lesions are seen, the cornea usually is hypoesthetic. Iritis may be associated with HSV keratitis and is characterized by miosis, photophobia, ocular pain, and foreign-body sensation. Vision may be decreased if the epithelial disease involves the visual axis.²⁷⁸ Epithelial HSV may be atypical, may be more severe, and may be more complicated in patients receiving topical steroids and in immunocompromised patients.

Treatment with topical trifluridine or ganciclovir should be strongly considered in all cases of HSV epithelial keratitis, and due to the risk of visual loss, the argument can be made to use oral acyclovir concomitantly.¹¹⁴ For HSV stromal keratitis, topical steroids are effective in decreasing corneal scarring but should only be used by an ophthalmologist. When using a topical steroid, coverage with a topical antiviral agent such as trifluridine should always be included to reduce the risk for recurrent active viral proliferation. Ancillary treatments include cycloplegic eye drops to dilate the pupil and pain medications as needed.

Chronic suppression with oral acyclovir is effective in reducing the number of recurrences of HSV epithelial and stromal keratitis, especially in patients with stromal keratitis.^{274,278} Interferon also significantly adds to the efficacy of topical antiviral therapy, but the adverse side effects of interferon must be weighed against its potential benefits.²⁷⁴

External Ocular Infections With Varicella-Zoster Virus

Childhood varicella infection (chickenpox) is commonly accompanied by conjunctivitis. Vesicles, ulcers, or both occur occasionally on the bulbar or palpebral conjunctiva. Conjunctivitis associated with varicella infection does not result in permanent visual sequelae. Corneal involvement rarely occurs and typically heals without sequelae. Occasionally it may result in stromal scarring and produce irregular astigmatism and reduced vision.

After primary varicella infection occurs, the virus may persist in latent form in the trigeminal nerve ganglia. Herpes zoster ophthalmicus occurs when the ophthalmic division of the trigeminal nerve is affected by reactivation of the virus. The condition occurs more commonly in immunocompromised patients, and recurrences occur infrequently except in these patients. For this reason, testing for immunocompromise, including HIV, should be considered in individuals with herpes zoster who are otherwise presumed to be immunocompetent.^{157,159,166}

The diagnosis of herpes zoster ophthalmicus is almost always made on the basis of the characteristic clinical feature of a painful, tender vesicular eruption of one V-1 dermatome. Ocular involvement may include keratitis and uveitis. Corneal epithelial lesions may appear dendritiform, with or without subepithelial infiltrates. Uveitis may occur with or without associated keratitis. Usually the uveitis is mild, but occasionally it may be severe, especially in immunocompromised patients, with the formation of a hypopyon (pus in the anterior chamber) or a hyphema. Immunofluorescence testing of vesicular base scrapings or viral cultures may be helpful if the manifestation is atypical or the diagnosis is in doubt.¹⁶²

Treatment of herpes zoster ophthalmicus involves the administration of oral or intravenous acyclovir. Treatment is most effective when initiated within 72 hours of the appearance of vesicles. The keratitis and uveitis do not respond to topical antiviral therapy.⁷⁰ Occasionally topical steroids may be helpful in treating varicella keratitis and uveitis, but such treatment should be administered under the direction of an ophthalmologist.¹⁸¹

Chlamydial Conjunctivitis and Trachoma

Chlamydia spp. can cause conjunctivitis and trachoma. *Chlamydia psittaci* rarely causes ocular disease in humans. *Chlamydia trachomatis*, however, has numerous serotypes that affect the eye. Serotypes A, B, Ba, and C

cause trachoma, and serotypes B, C, D, Da, D-, E, F, G, H, I, Ia, J, and K cause inclusion conjunctivitis, including neonatal inclusion conjunctivitis. Neonatal chlamydial conjunctivitis is addressed in the discussion of neonatal conjunctivitis. Inclusion conjunctivitis in older children and adults is a subacute or chronic inflammation of the conjunctiva. The condition may be unilateral or bilateral. A mucopurulent discharge typically occurs, as do follicles on the bulbar and perilimbal conjunctiva. Preauricular lymphadenopathy is a common feature. Punctate epithelial keratitis with subepithelial infiltrates and a superior micropannus (i.e., vascular growth on the upper edge of the cornea) may develop.⁶³

The differential diagnosis of inclusion conjunctivitis includes viral and bacterial conjunctivitis, molluscum contagiosum, and toxic keratoconjunctivitis from chronic administration of topical agents. Laboratory testing may be necessary to confirm the diagnosis. Giemsa staining of conjunctival scrapings may demonstrate the classic intracytoplasmic inclusions. A fluorescent antibody detection test or an enzyme immunoassay can be used for a rapid diagnosis.²⁷⁸ Chlamydial cultures may be needed when the diagnosis remains in doubt.

Treatment consists of oral erythromycin or doxycycline if systemic infection is suspected. Topical erythromycin or tetracycline alone four times each day for 7 days is effective treatment of infection limited to the conjunctiva.^{63,278} Moxifloxacin has been shown to be effective against chlamydia but is not yet the recommended treatment of choice.

Trachoma, a chronic blinding conjunctivitis, remains a prominent etiology of blindness worldwide, ranking sixth overall, causing 4% of all blindness. It is a disease of impoverished populations that is exacerbated by inadequate supplies of water and poor hygiene and sanitation. Trachoma seldom is seen in fully developed countries. In the United States, it is encountered on Native American reservations in the Southwest and in individuals from endemic foreign areas. Eye-seeking flies play an important role in transmission of *Chlamydia* from one person to another.²⁷⁸

Trachoma causes blindness by producing chronic inflammation of the palpebral conjunctiva of the upper eyelid with secondary scar formation. Contracture of the scars causes entropion of the eyelid and trichiasis (cilia rubbing on the cornea). After many years of infection and reinfection this leads to corneal neovascularization, opacification, and vision loss.^{277,288} Less commonly, the cornea may be infected directly. The complete course of the disease from initial infection to blindness generally takes decades. Children do not become blind from trachoma, but they are the most significant constant chronic reservoir of the disease.

The diagnosis of trachoma usually is made on the basis of clinical findings alone. The disease passes through characteristic stages, from simple inflammation to scarring, entropion, and trichiasis. Multiple stages may coexist in various parts of the eyelids. The World Health Organization classifies the stages of trachoma as follows: TF, trachomatous follicular response; TI, diffuse trachomatous conjunctival inflammation; TS, trachomatous scarring of the palpebral conjunctiva; TT, trachomatous trichiasis; and CO, trachomatous corneal opacification. In the pediatric population, physicians usually encounter only stages TI and TF.^{288,312} The scars on the palpebral conjunctiva, referred to as *Arlt lines*, are linear and multidirectional. Slit-lamp examination may reveal a superior limbal corneal micropannus and Herbert pits (i.e., hollowed-out areas at the superior limbus), which represent sites of resolved follicles.

Treatment of trachoma now consists of periodic dosing of susceptible populations with azithromycin or, if azithromycin is not available, topical tetracycline or erythromycin ointment instilled twice daily for 2 months, as well as improved sanitation and hygiene to prevent recurrence.²⁷⁸ Trachoma can be self-limited if hygiene alone is improved.²⁷⁷ In children older than 8 years of age, doxycycline should be administered orally daily for 40 days. Erythromycin can be substituted in younger children or in patients intolerant of doxycycline.

Neonatal Conjunctivitis

Neonatal conjunctivitis, or ophthalmia neonatorum, is a common vision-threatening disorder throughout the world, although it has been relegated to a position of secondary importance in the fully industrialized world, where screening and prophylactic measures are widespread. It remains a significant cause of childhood ocular morbidity in poor countries.

Dilute topical silver nitrate solution instilled just after birth for prophylaxis against ophthalmia neonatorum was the first treatment used. In the 1880s it was responsible for reducing the prevalence of gonococcal ophthalmia neonatorum from 10% to 0.17% of live births in Europe.²⁷⁸ Silver nitrate has been largely supplanted by other preparations; where it is used, a mild, self-limited chemical conjunctivitis can occur.²⁰⁸ It lasts 2 to 4 days and resolves with no treatment. Topical erythromycin largely has replaced silver nitrate in developed countries, because it is effective and does not produce a chemical conjunctivitis.¹¹⁹ In the developing world, dilute povidone iodine solution, 2.5%, has proved to be a remarkably effective and inexpensive measure for prevention of *N. gonorrhoeae* neonatal conjunctivitis when instilled immediately after birth.¹³⁶

In areas of regional conflicts, political instability, and burgeoning refugee populations, even such simple measures are often impossible.^{98,119} Causes of neonatal conjunctivitis are highly variable among populations. In areas that use silver nitrate or povidone iodine drops for prophylaxis, chemical conjunctivitis is a common cause of neonatal conjunctivitis.²⁰⁸ Infectious conjunctivitis occurs in 0.5% to 6.0% of live births in the United States. The leading infection is *C. trachomatis*.^{18,124,259,278}

Neonatal infection is caused by ocular exposure to contaminated maternal discharge during normal birth, although it may occur in infants born by cesarean section, especially if the membranes rupture prematurely. Other important infectious agents that may cause ophthalmia neonatorum are *N. gonorrhoeae* and *S. aureus*.^{97,266} Bacteria that normally reside in the vaginal or gastrointestinal tract occasionally are implicated in ophthalmia neonatorum.

Such bacteria include *Streptococcus* spp., *Haemophilus* spp., *Pseudomonas aeruginosa*, *Moraxella* spp. including *Moraxella catarrhalis*, *N. meningitidis*, *E. coli*, and *Enterobacter cloacae*.^{249,273} Viruses occasionally produce neonatal conjunctivitis. Rarely HSV may cause keratoconjunctivitis.⁹⁸ It is associated with distinctive vesicular skin changes and systemic signs, and the diagnosis seldom is in doubt.¹²

Life-threatening HSV meningoencephalitis is a serious potential complication of HSV ophthalmia neonatorum.²⁰¹ Other viruses occasionally implicated include adenovirus, coxsackievirus A9, cytomegalovirus (CMV), and echovirus.²⁷²

Certain clinical features may help establish the specific etiologic diagnosis in cases of ophthalmia neonatorum (Table 61.1), but considerable overlap in findings exists, and physicians cannot rely on the history and physical examination alone to make a definitive diagnosis. Even when all appropriate investigative modalities are used, the cause may remain unknown in some cases.

Variations in the time of onset after birth, severity of inflammation, and character of the ocular discharge are common, and though none is considered pathognomonic of a specific infectious process, general considerations are worth reviewing.²⁴⁹ Silver nitrate chemical conjunctivitis typically begins during the first 48 hours of life and produces a watery discharge with mild inflammation. It is self-limited and resolves within 48 to 72 hours of its appearance.²⁰⁸ *C. trachomatis* conjunctivitis generally begins 1 to 21 days after birth and usually is apparent by day 7. A moderately copious mucopurulent discharge may be present but can be variable.^{124,198} *S. aureus* conjunctivitis also begins during the first 3 weeks of life and can produce a moderately profuse mucopurulent discharge. Many other bacterial agents produce an overlapping clinical

picture. Conjunctivitis caused by *N. gonorrhoeae* ordinarily begins somewhat earlier, usually by the third day of life, but it may appear as late as 3 weeks after birth. The hallmark is a copious, hyperpurulent discharge that can reaccumulate in a matter of minutes after it is removed. *N. gonorrhoeae* can penetrate an initially intact cornea and result in perforation of the eye and endophthalmitis.^{121,252,273} Conjunctivitis caused by gastrointestinal flora often begins within a few days of birth and can produce a copious purulent discharge.

Viral causes of ophthalmia neonatorum are rarer in occurrence. HSV infection may begin during the first 3 weeks of life and usually produces a serous or serosanguineous discharge.^{98,201} Other viruses have highly variable characteristics, but a serous discharge is a common finding.

The differential diagnosis of neonatal conjunctivitis includes congenital glaucoma, dacryostenosis with or without dacryocystitis, keratitis, and uveitis. Dacryostenosis is manifested as epiphora and a watery or purulent discharge. Occasionally conjunctivitis may develop. Because epiphora caused by congenital dacryostenosis ordinarily is not seen until the second or third week of life, it rarely is a serious consideration. Newborns with congenital glaucoma often are photophobic and irritable.²⁹⁸ They may exhibit increased tearing, conjunctival injection, corneal edema, and enlargement of the ocular globe (buphthalmos). Both keratitis and uveitis most often are accompanied by photophobia and pain. The discharge with keratitis can vary but with bacterial causes is purulent. The discharge with uveitis, if present, is watery.

Laboratory testing is important in establishing a specific diagnosis and should include Gram and Giemsa stains, a chlamydial immunoassay, and cultures for aerobic and anaerobic bacteria. Cotton-tipped swabs should be used to obtain material for culture from the conjunctival fornices. Viral and chlamydial cultures and immunoassays can be considered but usually are unnecessary.^{17,281} Gonococcal immunoassay and HSV immunochemical tests are available but not in widespread use.

The initial treatment of neonatal conjunctivitis depends on the suspected infectious agent. Broad-spectrum treatment should be considered if the diagnostic possibilities cannot be narrowed. Silver nitrate-induced conjunctivitis is self-limited and does not require treatment. *C. trachomatis* conjunctivitis is treated with tetracycline (1%) or erythromycin (0.5%) ointment four times daily for 3 weeks and with systemic erythromycin for 2 to 3 weeks to prevent or to treat chlamydial pneumonia. Sulfonamides can be used to treat chlamydial conjunctivitis if erythromycin is not tolerated. Topical antibiotics alone are insufficient for the treatment of neonatal *Chlamydia* infection.^{109,120,124} Staphylococcal conjunctivitis can be treated with erythromycin ointment or a variety of other topical antimicrobial agents every 4 to 6 hours for 3 to 7 days. Appropriate systemic antibiotic treatment should be considered if the infection is particularly severe.²⁷⁸

N. gonorrhoeae infection requires systemic treatment in all cases. Aqueous penicillin G can be considered if resistant strains are unlikely. However, one dose of intramuscular ceftriaxone is the treatment of choice in the United States because it is effective against all *N. gonorrhoeae* strains.^{14,233} Eyes should be irrigated with saline every hour until the discharge clears and then in reduced frequency as necessary to reduce the risk for the development of corneal infection. This interval usually is 24 to 48 hours after the initiation of systemic treatment.

Penicillin G drops are recommended by some ophthalmologists, but such drops do not appear to improve the overall prognosis or speed of recovery.

HSV neonatal conjunctivitis is treated with systemic acyclovir in appropriate doses for as long as 3 weeks.⁹⁸ Treatment should be instituted on an emergency basis because of the potential for the development of serious permanent neurologic sequelae and death if treatment is delayed. Topical ophthalmic trifluridine or ganciclovir also should be applied to the eyes four times daily for 2 to 3 weeks.

Prevention of ophthalmia neonatorum is simple and requires only instillation of an antibiotic or antiseptic agent within the first hour after birth. Silver nitrate drops (1%), erythromycin ointment (0.5%), and tetracycline ointment (1%) all are effective treatments against *N. gonorrhoeae* and *C. trachomatis*.^{120,278} A 5% solution of povidone-iodine also has been effective and economical in prophylaxis against a variety of agents, including gonococcal neonatal conjunctivitis. It may be

TABLE 61.1 Clinical Characteristics of Neonatal Conjunctivitis Caused by Various Agents

Agent	Day of Life at Onset	Discharge
Silver nitrate	1 (0–2)	Serous
<i>Chlamydia trachomatis</i>	7 (1–21)	Mucopurulent
<i>Staphylococcus aureus</i>	5 (1–21)	Mucopurulent
<i>Neisseria gonorrhoeae</i>	3 (0–21)	Purulent
Other bacteria	7 (1–21)	Mucopurulent
Herpes simplex virus	5 (0–21)	Serosanguineous
Other viruses	Not established	Probably serous

particularly useful in developing countries.¹³⁶ As with other sexually transmitted diseases, neonatal conjunctivitis caused by *N. gonorrhoeae*, *C. trachomatis*, or HSV should be addressed according to standard public health policies, with reporting, investigation, and case identification as required by local law.

KERATITIS: CORNEAL INFLAMMATION

The cornea, with its overlying tear film, is the major refracting component of the human eye. Keratitis means inflammation of the cornea. Microbial keratitis means inflammation of the cornea caused by infection with a microorganism.

Any irregularity of the corneal tear film, the surface of the cornea itself, or an opacity of the cornea involving the central visual axis may impair vision. The cornea is composed of five distinct layers: the epithelium, Bowman's layer, the stroma, Descemet's membrane, and the endothelium. The epithelium is several layers thick and, when healthy, can regenerate without scarring after an injury or other insult. The Bowman membrane lies beneath the epithelium. It does not regenerate, and it heals with a scar when injured. The stroma is the thickest part of the cornea. It is composed of regularly arranged collagen fibrils embedded in a matrix of mucoproteins and glycoproteins. Like the Bowman membrane, the stroma heals with scarring.

Descemet's membrane is the basement membrane of the corneal endothelium. It can regenerate after an insult and does not opacify. The innermost layer, the endothelium, is derived from neuroectoderm and consists of a single layer of cells that do not have significant regenerative capacity. The cornea is an avascular structure that is clear because of the regular arrangement of the collagen fibers in the stroma and the dehydrating pumping action of the endothelium. The cornea will become edematous and opacify if the endothelium is significantly damaged or diseased. The external corneal surface is protected from injury and exposure by the eyelids. Reflex tearing in response to mechanical irritation provides further protection. The blink response to threat and the antimicrobial properties of the tear film further protect the cornea from injury and infection.

Patients with keratitis usually have erythema of the perilimbal bulbar conjunctiva (limbal or ciliary flush) and pain. Additional complaints may include decreased vision and photophobia. The diagnosis of keratitis depends on the presence of a corneal epithelial or stromal infiltrate. The infiltrate is verified by slit-lamp examination and can be extremely difficult to see in infants and uncooperative or frightened children. Ideally the patient is examined with a slit lamp; sometimes sedation is required for this. Stains and cultures are usually required to establish the diagnosis, preferably before topical antibiotics are started, so an ophthalmologist should be consulted promptly. Rarely a biopsy of the cornea is needed to obtain material for culture. Even more rarely, a corneal transplantation is required to stop progression of an infection or to treat a corneal perforation. Exact etiologic diagnosis is based on clinical findings and on examination of stains and cultures.

Isolated Epithelial Keratitis

Keratitis can be classified according to the layer of cornea involved. Most infections involve the epithelium and/or the stroma. Isolated epithelial keratitis usually is caused by one of several viruses: HSV, varicella-zoster virus (VZV), adenovirus, EBV, and the (rubeola) measles virus. The first three organisms have been discussed in an earlier section.

EBV causes HSV-like dendritic corneal epithelial lesions; stromal disease also may occur. The lesions are self-limited and do not respond to antiviral therapy.¹⁸⁰ Measles keratitis usually consists of transient epithelial infiltrates, which resolve without permanent sequelae.¹⁴⁶ In malnourished children with vitamin A deficiency, measles represents a serious threat to life and to vision. Deep corneal ulcers may develop during the first few days of measles infection. Vitamin A deficiency remains the most common cause of pediatric blindness worldwide, almost exclusively involving children in developing countries. Measles is a common comorbidity factor. When a vitamin A-deficient child develops measles and keratitis, rapid progression leading to corneal perforation and ultimate loss of the eye may occur.^{24,96} Whether the ulcers are caused by direct measles virus infection, by the keratomalacia

(corneal melting) of vitamin A deficiency, or by some combination of these factors is still not entirely clear.

Measles immunization programs plus periodic mega-vitamin A dosing programs for susceptible children under 6 years of age greatly reduce childhood blindness and childhood mortality in developing countries.

Stromal Keratitis

Syphilis and certain parasitic and viral infections can cause a nonsuppurative keratitis isolated to the corneal stroma. Congenital syphilis produces interstitial (stromal) keratitis in children, although the condition usually does not become apparent until late in the first decade of life. An indolent, peripheral corneal haze develops and slowly progresses centrally. Ghost vessels devoid of blood flow are seen in the corneal stroma on slit-lamp examination.²⁸⁰ The condition is manifested as a bilateral stromal process²⁵⁵ in 80% of cases and is accompanied by transient iritis, iridocyclitis, or scleritis at some point in the course of the disease. When ocular syphilis is diagnosed, systemic infection is present by definition. The systemic disease must be treated according to accepted guidelines.

Bacterial Keratitis

Bacterial keratitis, usually involving a corneal ulcer, most often occurs after trauma that disrupts the normal integrity of the corneal epithelium. The trauma can be mild and occult, such as that caused by contact lens wear. *S. aureus*, *S. pneumoniae*, *P. aeruginosa*, and *Moraxella* spp. are the most common bacterial causes of severe necrotizing bacterial keratitis.^{10,164,197,295} Other organisms, such as *S. epidermidis*, *Actinomyces* spp., viridans streptococci, *Acanthamoeba*, and a variety of others, have been implicated in less severe cases. Accurate identification of the offending organism greatly facilitates effective treatment. A specimen is obtained by scraping the edge of the ulcer with a sterile platinum spatula. Smears should be fixed in 70% methanol, not by heat, and Gram stain for bacteria and acridine orange stain for fungi and *Acanthamoeba* are recommended. The yield of culture-positive cases is higher in laboratories skilled in handling corneal cultures. Material for culture should be inoculated onto fresh media such as blood and chocolate agar (aerobes and facultative anaerobes), Sabouraud agar (fungi), and thioglycolate broth (anaerobic bacteria). Thayer-Martin agar should be plated if *N. gonorrhoeae* is suspected. Initial treatment is based on the resulting stains (Table 61.2) and modified pending cultures (Table 61.3).^{20,163}

Typically patients are started on frequent fortified tobramycin and ceftazidime drops until culture results become available. Medical treatment of bacterial keratitis includes fourth-generation fluoroquinolones, fortified topical antibiotics, and, occasionally, subconjunctival antibiotic injection (see Table 61.2).^{45,211,278} Antibiotics are administered as often as every 15 to 30 minutes initially and then continued hourly until there has been definite improvement, usually first manifested by improvement in pain. Systemic antibiotics are required only for gonococcal, chlamydial, and onchocercal keratitis, as well as for actual or threatened perforation of the cornea, extension of infection to the sclera, or worsening of the process during topical or periocular treatment. Topical steroids have been found to be beneficial if the resulting inflammation threatens to destroy the mechanical or optical integrity of the cornea, but steroids are never used as isolated treatment.^{268,278}

Two important corneal sequelae of previously discussed eyelid blepharitis are staphylococcal marginal keratitis and phlyctenulosis. Both are thought to represent hypersensitivity reactions by the ocular surface to bacterial toxins. Symptoms include eye redness, irritation, and itching, and patients usually present late and carry the misdiagnosis of allergic conjunctivitis due to overlap of symptoms. Marginal keratitis usually affects the peripheral cornea (especially inferiorly) and appears as multiple, small, faint gray spots in the subepithelium. Phlyctenulosis is a more severe sequela and appears as a gelatinous aggregation (single or multiple) of inflammatory cells. Treatment of phlyctenulosis is particularly important due to cumulative risk of corneal scarring and its effect on vision. Combination antibiotic-steroid eye drops or ointments are effective in improving both the bacterial load and the hypersensitivity component. Consideration should also be made for using a short course of oral azithromycin for these same reasons.^{47,75}

TABLE 61.2 Treatment of Keratitis Based on Smear Morphology

Organism	ANTIBIOTIC	
	Ocular	Systemic ^a
Gram-positive cocci, gram-positive bacilli	Cefazolin ^b	Nafcillin, IV
Gram-positive filaments	Amikacin ^c	Trimethoprim-sulfamethoxazole, IV
Gram-negative cocci	Ceftriaxone ^b or ciprofloxacin ^{c,d}	Ceftriaxone, IV or IM
Gram-negative bacilli	Tobramycin ^b	Tobramycin, IV
Acid-fast bacilli	Amikacin ^c	
Hyphal fragments	Natamycin, ^c fluconazole ^e	Fluconazole, PO
Yeasts	Amphotericin B, ^c fluconazole ^e	Fluconazole, PO
Cysts, trophozoites	Polyhexamethylene, biguanide, ^c paromomycin, ^c and propamidine isethionate ^c	Itraconazole, PO

IM, Intramuscularly; IV, intravenously; PO, orally.

^aStandard age-appropriate mg/kg dosages.

^bTopical and periocular use only.

^cTopical use only.

^dUse in children age ≥12 years.

^ePeriocular use only.

TABLE 61.3 Treatment Based on Identification of Organisms

Organism	ANTIBIOTIC	
	Ocular	Systemic
<i>Micrococcus</i> , <i>Staphylococcus</i> (penicillin-resistant)	Cefazolin ^a	Nafcillin, IV
<i>Micrococcus</i> , <i>Staphylococcus</i> (methicillin-resistant)	Vancomycin ^a	Vancomycin, IV
<i>Streptococcus</i>	Penicillin G ^a	Penicillin G, IV
<i>Enterococcus</i>	Vancomycin ^a and gentamicin ^a	Vancomycin, IV, and gentamicin, IV
Anaerobic gram-positive coccus	Penicillin G ^a	Penicillin G, IV
<i>Corynebacterium</i> spp.	Penicillin G ^a	Penicillin G, IV
<i>Mycobacterium fortuitum-chelonae</i>	Amikacin ^b	Amikacin, IV, ^a or clarithromycin, PO
<i>Nocardia</i>	Amikacin ^b	Trimethoprim-sulfamethoxazole, IV
<i>Neisseria gonorrhoeae</i>	Ceftriaxone ^a	Ceftriaxone, IV or IM
<i>Pseudomonas</i> spp.	Ceftazidime ^a Tobramycin ^a	Ceftazidime, IV or IM
Other aerobic, gram-negative bacilli	Ceftazidime ^a Tobramycin ^a	Ceftazidime, IV or IM
Filamentous fungi	Natamycin ^b Fluconazole ^c	Fluconazole, PO
<i>Candida</i> spp.	Amphotericin B ^b Fluconazole ^c	Fluconazole, PO
<i>Acanthamoeba</i>	Polyhexamethylene biguanide, ^b paromomycin, ^b and propamidine isethionate ^b	Itraconazole, PO

IM, Intramuscularly; IV, intravenously; PO, orally.

^aTopical and periocular use.

^bTopical use only.

^cPeriocular use only.

Fungal Keratitis

The most common causes of fungal keratitis include *Candida*, *Aspergillus*, and *Fusarium*. Mycotic keratitis associated with the filamentous fungi *Aspergillus* and *Fusarium* is thought to occur with trauma, whereas keratitis caused by *Candida* is associated more commonly with a preexisting ocular (e.g., dry eye) or systemic (e.g., diabetes mellitus or immunosuppression) condition.²⁸⁴ Fungal keratitis tends to be relatively indolent in contrast to bacterial keratitis. Typically white stromal infiltrates with irregular and indistinct feathery borders are detected. Satellite lesions, separated from the main lesion, may be evident. Mild iritis is common. Severe iritis with hypopyon can occur but is an infrequent manifestation.²¹² For possible fungal keratitis, an acridine orange stain is recommended, and culture on a Sabouraud agar plate is indicated. Hyphal fungi are treated with topical natamycin, topical fluconazole, systemic fluconazole, or some combination of these medications. Yeasts are treated with topical or systemic amphotericin B, fluconazole, or both.⁹⁵

Protozoan Keratitis

Protozoan keratitis is a particularly serious vision-threatening process. It usually is caused by *Acanthamoeba* and occurs more frequently in wearers of soft contact lenses. Use of homemade saline solution is a significant risk factor and should be discouraged.³⁷ Amoebae are ubiquitous organisms in soil, water, and air. They have been identified in hot tubs and in the feces of domestic animals.¹⁸⁰ People living in rural areas may be at special risk.

Acanthamoeba keratitis has been reported in children without a history of contact lens use or trauma.⁶⁴ *Acanthamoeba* corneal ulcers are pleomorphic.¹³⁵ Older lesions may exhibit a ringlike infiltrate around a central ulcer. Iritis or iridocyclitis may be intense, and severe pain out of proportion to exam findings is a hallmark of the disease. Acridine orange and calcofluor white stains aid in establishing an early diagnosis.¹⁷⁸ Tandem scanning confocal microscopy of corneal specimens may increase diagnostic accuracy, and the organism may grow on blood and chocolate agar.^{37,174,225} Treatment of *Acanthamoeba* keratitis is complex and many

times unsuccessful. Topical application of polyhexamethylene biguanide (0.02%),¹⁵⁸ chlorhexidine (0.02%), paromomycin (0.1%), or propamidine isethionate (Brolene) drops can be attempted. Oral itraconazole (Sporanox) has been used successfully in adults.^{154,174,184} Cycloplegic agents are recommended for comfort, and pain medications are often required.

Corneal transplantation is performed if the infection progresses despite treatment, if perforation occurs, or if significant corneal visual axis opacification remains after the active infection is eradicated. Infection can recur even in the transplanted cornea.²³²

Onchocerca volvulus is a filarial parasite that causes river blindness (i.e., onchocerciasis). The disease is endemic in sub-Saharan West Africa, in isolated areas of east and central Africa, and in some areas of central and northern South America. The organism is transmitted by the bite of a blackfly of the family Simuliidae.²⁴³ Larvae migrate to subcutaneous tissue and pass through several molts to become adult worms, which encapsulate in nodules and produce microfilariae that pass into blood, skin, and other organs, including the eyes. The conjunctiva, cornea, aqueous humor, vitreous, retina, uveal tract, sclera, and optic nerve all may be infested. Corneal involvement can lead to vision loss caused by corneal opacification, but most severe vision loss is caused by choroidal, retinal, and optic nerve disease.¹¹⁸ Although children are often infected, blindness usually does not occur until they reach the third or fourth decade of life.^{287,298}

Treatment of onchocercal infection is administration of ivermectin every 6 to 12 months to all individuals living in endemic areas. Ivermectin kills the microfilariae but not the adult worms, which live in subcutaneous nodules and remain until their death.²⁸³ The adult worm may live 10 or more years. Because of the long life span, ivermectin should be taken every 6 months for at least 10 years to treat microfilariae as they develop.

Microsporidia are intracellular protozoa that represent a new emerging ocular pathogen. Interest in the organism increased in the past few decades because of its association with HIV and acquired immunodeficiency syndrome (AIDS). The ocular manifestation corresponds to both the immune status of the patient and the genus of microsporidia involved.¹⁴⁴ Typically keratoconjunctivitis occurs in immunocompromised individuals, while stromal keratitis is more commonly seen in immunocompetent individuals. Keratoconjunctivitis is manifested as bilateral conjunctival inflammation and epithelial keratopathy, which may lead to decreased vision. Stromal keratitis is manifested as an insidious diskiform keratitis with uveitis similar to that seen in HSV stromal keratitis and may require penetrating keratoplasty because of perforation or scarring. Potassium hydroxide plus calcofluor white and acid-fast stains are thought to be the most efficient means of establishing the diagnosis of microsporidial keratitis.¹⁴³ Transmission electron microscopy provides specificity in identification of the genus and possibly the species, but it may lack sensitivity and is laborious.¹⁴⁴ Knowledge of the genus and species may help guide management. Albendazole, fumagillin, itraconazole, metronidazole, and topical propamidine isethionate have been used as therapeutic agents.^{53,144}

INFECTIONS PRIMARILY INVOLVING THE UVEA

The uveal tract is the vascular middle coat of the eye. It is situated between the sclera and the retina. Its major function is to provide nourishment for intraocular tissues, including the retina, lens, and cornea. The uveal tract is composed of the iris, ciliary body, and choroid.

Uveitis is a nonspecific term for inflammation of the uvea. If the inflammatory process primarily affects the iris, it is called *iritis*. If the ciliary body is involved, the process is called *cyclitis*. If these two structures together are involved, the process is called *iridocyclitis* (i.e., anterior uveitis). The term *intermediate uveitis* (i.e., pars planitis) applies to inflammation in the region of the ciliary body and peripheral retina. The term *posterior uveitis* usually applies to combined inflammation of the retina and choroid, also called *chorioretinitis*. If the choroid alone is involved, it is called *choroiditis*; inflammation of the retina alone is called *retinitis*. Because of the thinness and close apposition of these two tissue layers, inflammation in one layer frequently “spills over” into the other. The vitreous body occupies the central area of the eye behind the lens. It is composed of water, mucopolysaccharides, and collagen. Although transparent in a normal, healthy eye, the vitreous is subject

to inflammation or *vitritis*, usually as a result of inflammation in adjacent retinal tissue or in the pars plana.

Causes of uveitis are numerous but can be categorized into two main groups: infectious and noninfectious. Infectious causes are discussed in this chapter. Uveitis in any area of the eye may result in pain, conjunctival or episcleral hyperemia, photophobia, tearing, and decreased vision, although these symptoms vary relative to the site and the aggressiveness of the inflammation.

With slit-lamp examination, the hallmark of anterior uveitis is the presence of leukocytes in the anterior chamber, called *cell*, and the finding of hazy, proteinaceous aqueous humor, called *flare*. The cell and flare components are graded independently on a 1+ to 4+ scale. If present in sufficiently great numbers, leukocytes can precipitate in the anterior chamber (with location dependent on gravity) and form a mass called a *hypopyon*. The cells can aggregate on the back of the cornea and create fine, medium, and large lesions known as *keratic precipitates*. The conjunctiva usually is injected or hyperemic. With chronic inflammation, the border of the pupil often adheres to the anterior surface of the lens. Such adhesions are called *posterior synechiae* and may cause the pupil to have an irregular shape and size, as well as poor reactivity to light. Chronic or recurrent anterior segment inflammation may lead to the formation of a cataract. Iris nodules or atrophy may develop with long-standing inflammation. Anterior vitreous cells may occur as a spillover phenomenon in the setting of a prolonged or vigorous anterior chamber reaction. Although inflammatory effects on the ciliary body generally compromise its production of aqueous humor and thereby reduce intraocular pressure, cellular and proteinaceous debris can occlude aqueous humor outflow channels and lead to elevated intraocular pressure.

Inflammation primarily involving the posterior segment of the eye usually leads to decreased vision, which may be the symptom for which treatment initially is sought. Pain may be minimal or absent. Inflammatory lesions of the retina and choroid also may lead to the development of cellular debris in the vitreous and cause the patient to perceive “floaters.” Initially, the borders of the retinal or choroidal inflammatory foci often are indistinct and cream-colored. In the healing phase, the borders of these lesions increasingly become distinct, and a defined, partially pigmented scar results. Inflammatory perivascular sheathing of the retinal vessels may occur as well. Involvement of the macula with edema or exudates may result from inflammation of the posterior segment, and long-standing edema may evolve into a cystic configuration and cause loss of central visual acuity. The optic nerve may exhibit an inflammatory response; if the optic disc is so involved, the response is called *papillitis*. Inflammatory debris also may be found in the vitreous.^{4,215,315}

Epidemiology

In the United States, most uveitis cases have noninfectious causes. Large samples demonstrate a predominance of anterior rather than posterior uveitis. The most common category of anterior uveitis is idiopathic; the most common infectious cause of anterior uveitis is herpetic kerato-uveitis (simplex and zoster). Posterior uveitis is caused most frequently by *Toxoplasma gondii*. In developing nations, infectious uveitis plays a larger role. In West Africa, *T. gondii* probably accounts for most cases of intraocular inflammation.^{240,241}

Viral Uveitis

Herpes Simplex Virus

Most of the uveal inflammation associated with HSV (typically iridocyclitis) results from the corneal disease. Occasionally a patient will have iritis as an isolated finding, but most patients with ocular HSV demonstrate conjunctivitis, keratitis, chorioretinitis, or retinal vasculitis.²³⁵ The iritis may require treatment with antivirals as prophylaxis against the development of corneal epithelial disease.^{294,315}

Varicella-Zoster Virus

Occasionally varicella infection (i.e., chickenpox) may be associated with a transient iritis that requires no treatment. Although rare, cases of unifocal choroiditis causing visual loss but responsive to acyclovir in children with primary varicella have been reported.¹⁹⁵

Herpes zoster virus may cause iridocyclitis during the acute stage of the disease; the anterior chamber reaction can persist or recur long after resolution of the cutaneous component of the condition. Herpes zoster always should be considered in the differential diagnosis of chronic unilateral iridocyclitis. Topical steroids are indicated for iritis, with the addition of oral or intravenous acyclovir for severe cases. Segmental iris atrophy is a characteristic sequela of herpes zoster uveitis. Glaucoma, hyphema, retinitis, vasculitis, and extraocular muscle palsy occasionally occur in patients with herpes zoster ophthalmicus. In a profoundly immunosuppressed patient, VZV can cause a devastating retinitis known as *progressive outer retinal necrosis*.¹⁶² The visual prognosis is poor.

VZV and HSV-2 have been implicated as causes of acute retinal necrosis syndrome. Patients in whom this syndrome is diagnosed range from 13 to 71 years of age, with an average age of 43 years. The syndrome typically occurs in healthy patients. The virus causes a triad of acute vitritis, retinal vasculitis, and peripheral necrotizing retinitis and is bilateral in 33% of patients. Treatment consists of intravenous acyclovir. Prophylactic laser photocoagulation may prevent retinal detachment. The visual prognosis is guarded.^{26,162}

Epstein-Barr Virus

Ocular EBV involvement has been reported primarily in patients with infectious mononucleosis. Follicular conjunctivitis may be diagnosed in 2% to 40% of patients. Corneal stromal inflammation, iritis, episcleritis, optic neuritis, and chorioretinitis occur less commonly. Systemic corticosteroids and acyclovir may be useful in treating sight-threatening complications of chronic intraocular inflammation from EBV infection.¹⁸² Postinfectious uveitis also has been described and is discussed later.

Enteroviruses

Coxsackievirus A24 and enterovirus 70 may cause a painful follicular conjunctivitis called acute hemorrhagic conjunctivitis. Rarely chorioretinitis may be diagnosed. Treatment of these infections primarily is supportive.²¹⁵

Rubella Virus

Rubella virus can cause congenital and acquired infections. Ocular manifestations of acquired rubella include conjunctivitis in 70% of patients, superficial keratitis, and iritis. Rarely retinitis has been reported.

Congenital rubella syndrome can be manifested as cataracts, glaucoma, microphthalmos, and retinitis. Cataracts occur in 15% of patients and glaucoma in 10%. Retinal examination reveals a salt-and-pepper fundus caused by the alternating pattern of hypopigmentation and hyperpigmentation of the retinal pigment epithelium. The prognosis for patients with retinitis alone usually is good, with vision between 20/20 and 20/40. Glaucoma resulting from rubella commonly requires surgery, as do the cataracts. Iritis is reported less commonly.^{142,182}

Mumps Virus

Ocular manifestations of mumps virus include dacryoadenitis, conjunctivitis, iritis, optic neuritis, and keratitis. Retinitis also has been reported. The prognosis for visual recovery from the retinitis is good, and sequelae of the iritis are rare occurrences.^{95,182}

Measles Virus

Measles virus can cause congenital and acquired infections. In congenital infections, a salt-and-pepper retinopathy and cataract formation may occur, similar to that found in rubella. Ocular manifestations in acquired measles include conjunctivitis and, much less commonly, retinitis, retinal vasculitis, and optic nerve edema.^{15,215}

Subacute Sclerosing Panencephalitis

Between 30% and 75% of patients with subacute sclerosing panencephalitis (SSPE or Dawson inclusion body encephalitis) have ocular findings. SSPE is caused by a variant of the measles virus; it differs from the wild-type virus by alteration or absence of viral M protein. Optic nerve edema, inflammation, and subsequent optic atrophy have been reported. Macular retinitis is a common finding, and the contiguous nonneural tissues (vitreous and choroid) almost never are involved. The visual prognosis of survivors is poor.^{210,215}

Creutzfeldt-Jakob Disease

The most common ocular manifestation of Creutzfeldt-Jakob disease is cortical blindness. Optic atrophy may result from degeneration of the neurons of the optic nerve.²¹⁵

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

As many as 75% of patients with advanced AIDS have ocular findings. Cotton-wool spots occur in more than 50% of patients and are bilateral in more than 80%. Cotton-wool patches represent focal infarctions of the neural layer of the retina and are the most common ocular finding in patients with AIDS. They generally produce no symptoms and do not decrease vision. These spots are white and fluffy and occur most commonly in the macular portion of the retina. They resolve in 4 to 6 weeks with no residual scars. Occasionally flame-shaped hemorrhages are detected as well. The retina and choroid in these patients may become infected with HSV, CMV, VZV, syphilis, tuberculosis, histoplasmosis, *Candida*, toxoplasmosis, and *Pneumocystis*, although in the highly active antiretroviral therapy (HAART) era, the incidence of CMV retinitis has declined, and its advance in existing cases has been slowed or halted. Symptomatic anterior uveitis in the absence of the aforementioned pathogens occurs rarely in patients with AIDS and may be caused by HIV itself.¹³⁷

Cytomegalovirus Infection

CMV infections may occur in preterm neonates and immunosuppressed patients, especially those with AIDS. In neonates with symptoms of CMV infection (i.e., low birth weight, microcephaly, jaundice, thrombocytopenia, hepatosplenomegaly, or petechial rash), congenital CMV infection²¹ (i.e., prenatal transmission) may be manifested in the fundus as chorioretinal scars (21%) and optic atrophy (7%).⁵⁰

CMV retinitis develops in approximately 30% of adult patients with AIDS, usually those with CD4⁺ counts less than 50/mm³.⁸⁰ In the pediatric AIDS population, CD4⁺ counts of less than 20/mm³ may be required for appearance of the retinitis.⁷⁶ The disease is less common in pediatric patients with AIDS. Patients with CMV retinitis have no external ocular signs but may complain of loss of vision. Children may not complain of such loss, and the problem may become apparent only after bilateral severe vision loss has occurred.⁷⁶ The retinal lesions of CMV typically are yellow-white and often are associated with hemorrhage. The retinitis generally follows a perivascular distribution. The retina becomes necrotic and eventually atrophies, with a gliotic scar. CMV optic neuritis also may develop. Treatment consists of intravenous or intravitreal ganciclovir, intravenous or intravitreal cidofovir, or intravenous foscarnet^{81,315} and can often be discontinued when the CD4⁺ count rises above 100/mm³.^{3,286}

Parvovirus Infection

Bilateral panuveitis has been reported to be associated with parvovirus B19 infection.¹⁷³

Human T-Cell Lymphotropic Virus Infection

Human T-cell lymphotropic virus is endemic in several regions of the globe: Japan, the Caribbean islands, and parts of central Africa. It probably is responsible for several cases of self-limited, occasionally recurrent uveitis in these regions.²⁰²

Lymphocytic Choriomeningitis Virus Infection

Lymphocytic choriomeningitis virus (LCMV) is an arenavirus endemic in mice; it is also reported in hamsters and is occasionally transmitted to humans by direct contact with the rodent or through aerosolization of its feces or urine. Postnatal exposure results in asymptomatic seroconversion or aseptic meningitis, but intrauterine infection can have devastating consequences. Spontaneous abortion, congenital hydrocephalus, psychomotor retardation, and chorioretinitis have been documented. Diffuse chorioretinal scarring identified postnatally may bode a grim visual prognosis. LCMV may be an underdiagnosed cause of unexplained congenital chorioretinitis. The diagnosis is confirmed by elevated LCMV antibody titers. A survey of severely retarded, visually disabled children revealed immunologic evidence pointing to LCMV as the cause of the visual loss in approximately half of those surveyed.^{187,190}

Viruses

Rift Valley fever virus. Rift Valley fever virus is an insect-borne virus. The arthropod vector directly inoculates the virus into the bloodstream of a host, resulting in end-organ infections, including the retina. Cattle and sheep are the primary host, and mosquitoes are the vector for transmission. Outbreaks have been reported in eastern and sub-Saharan Africa and South Africa. Uveitis and conjunctivitis can occur in the acute phase of the disease.^{70,260} A viral retinitis may occur 1 to 3 weeks after the illness. It may be unilateral or bilateral, affecting both the central and the peripheral fundus with hemorrhages, exudates, and retinal vasculitis.

Herpes B virus. Herpes B is an α herpes virus within the herpesvirinae family. Transmission to humans occurs via bites or scratches from infected monkeys where the virus is endemic. Infection may also occur via puncture wounds from contaminated objects.^{203,242}

Herpes B virus has been associated with ocular complications in persons handling monkeys.^{203,242} The reports suggest that the virus can cause retinal disease indistinguishable from acute retinal necrosis syndrome, with multifocal necrotizing retinitis and panuveitis in an immunocompetent host.

Influenza A virus. Influenza A virus is a pneumotropic virus with affinity to the branchial epithelial cells. It is transmitted by droplet infection.²³ Ocular manifestations in influenza include conjunctivitis, keratitis, iritis, and dacryoadenitis during the acute phase of the disease. Retinal involvement with influenza A virus has been reported. Retinitis of influenza A is typically bilateral and predominantly affects the macula with hemorrhages, exudates, and macular edema. Fluorescein angiography reveals diffuse vascular leakage. Optic disc edema may rarely be seen. The disease is typically self-limited, with return of vision to 20/20.²³⁰

West Nile virus. West Nile fever is a mosquito-borne infection caused by the West Nile virus. The vast majority (~80%) of cases have few or no symptoms, while most other cases present with flu-like symptoms. Less than 1% of infections are severe and result in CNS disease, especially in people of advanced age, the very young, or those who are immunocompromised. Diagnosis is usually made by enzyme-linked immunosorbent assay (ELISA) testing of the serum or CSF.

Fundus exam can be helpful in diagnosing West Nile virus infection. The most common retinal finding is the presence of multifocal chorioretinal target lesions (69% to 85%), usually bilateral. Other findings include retinal hemorrhages, vitritis, retinal vasculitis, and optic neuritis. Most ocular involvement is self-limited; however, less frequent lesions such as retinal vasculitis and especially optic neuritis may lead to permanent visual deficits.^{43,151}

Zika virus. Zika virus is a mosquito-borne Flavivirus that was first isolated in Uganda. For many decades after its discovery, infections were only known to occur in a narrow equatorial belt from Africa to Asia; however, in 2007 the virus spread eastward and reached pandemic levels in 2015–16. Zika infections in adults usually cause no or mild symptoms, but Zika can spread from a pregnant woman to her fetus, causing devastating birth defects including microcephaly and other severe brain malformations.

Ocular findings in infected adults have not yet been reported, but those in affected infants are becoming increasingly well described. The most common retinal finding is that of a hyperpigmentary retinopathy with propensity for the macula. Hemorrhagic retinopathy can also occur. Vigilance on the part of pregnant women (or those planning to become pregnant), mainly in the form of avoiding travel to endemic areas, is the only known prevention mechanism at this time.^{67,193}

Chikungunya virus. Infection by the chikungunya virus causes the sudden onset of a short fever with accompanying joint pains of long duration. Ocular manifestations are not frequent but include conjunctivitis, optic neuritis, iridocyclitis, episcleritis, retinitis, and uveitis.¹⁷⁹

Bacterial Uveitis

Syphilis

Syphilis (*Treponema pallidum*) should be considered as a possible cause in all cases of intraocular inflammation. Any patient with confirmed syphilitic uveitis should undergo a lumbar puncture to rule out asymptomatic neurosyphilis.

Ocular manifestations of congenital syphilis include interstitial keratitis, a mottled salt-and-pepper fundus, and chorioretinal scarring. Acute interstitial keratitis occurs as a late manifestation of congenital syphilis (5 to 25 years of age) and is thought to be a hypersensitivity response to treponemal antigen in the cornea. Patients complain of pain and photophobia and have a diffusely opaque cornea and anterior uveitis. Blood vessels invade the inflamed cornea and eventually are obliterated, leaving “ghost vessels” in the corneal stroma. Glaucoma may occur. A unilateral manifestation of interstitial keratitis suggests postnatally acquired syphilis.

Secondary syphilis may involve any layer of the eye. Episcleritis, scleritis, iridocyclitis (acute, chronic, or recurrent), iris capillary dilation (iris roseata), vascular papules of the iris (iris papulosa), inflammatory nodules (iris nodosa), choroiditis, chorioretinitis, and retinal vasculitis all have been reported, as have optic neuritis and subsequent atrophy.

Tertiary syphilis may have associated gummata of the iris and an Argyll Robertson pupil—a miotic, irregularly shaped pupil with loss of response to light but preservation of the near response. Intraocular inflammation seldom occurs at this stage.

Ocular inflammation secondary to syphilis should be treated as neurosyphilis. With the appropriate doses of penicillin G, the inflammation typically resolves rapidly. Occasionally topical regional steroids are required to control local inflammation. Treatment of ocular syphilis may lead, at least initially, to a vigorous local and systemic self-limited febrile response, presumably caused by liberation of spirochetal antigens or toxins. Topical oral corticosteroids may be required to quell this response, which is also known as a Jarisch-Herxheimer reaction.^{4,177,215}

Lyme Disease

A mild follicular conjunctivitis occurs in 11% of patients with stage 1 Lyme disease, caused by *Borrelia burgdorferi*. During the second and third stages, neuro-ophthalmic manifestations including cranial neuropathy (most often cranial nerves III, IV, VI, and VII), optic neuritis, bilateral keratitis, bilateral iridocyclitis, diffuse choroiditis, vasculitis, intermediate uveitis, and Parinaud oculoglandular syndrome may be seen. The most frequent manifestation of late Lyme disease is arthritis. Ocular inflammation occurs in approximately 4% of children with Lyme arthritis.¹³⁴ Early or localized Lyme disease may be treated with doxycycline (8 years of age and older) or amoxicillin. More advanced or persistent disease is treated best with intravenous ceftriaxone.⁶ Antibiotic treatment early in the course of the disease carries a better prognosis than does therapy initiated at later stages.²²

Leptospirosis

Leptospirosis may cause an anterior uveitis that occurs months after the acute infection. Leptospirosis is identified as an important cause of epidemic panuveitis in southern India; the most common posterior segment manifestations in this group are vasculitis and vitritis.⁴⁸

Tuberculosis

Any structure of the eye may be affected by tuberculosis. Allergic and infectious processes have been implicated as important causes of tuberculous uveitis. Anterior uveitis with or without keratitis has been attributed to tuberculosis, and choroiditis, optic neuritis, and orbital infections have been detected in cases of miliary tuberculosis. The most frequent manifestations of ocular tuberculosis are choroidal nodules and scars (so-called tuberculomas); anterior uveitis is an uncommon occurrence.³⁰ Treatment should be undertaken with the appropriate antituberculous medications. Corticosteroids often are necessary in conjunction with antimicrobial therapy.

Leprosy

Because *Mycobacterium leprae*, the cause of leprosy, grows best at lower temperatures, corneal infections predominate. Corneal involvement is associated with prominence of the corneal nerves, interstitial keratitis, and corneal hypoesthesia, but corneal opacities are often peripheral and not visually significant.⁵⁸ Uveal involvement in leprosy frequently is silent and accounts for a large number of the ocular complications from the disease.^{58,59}

Brucella Infection

Ocular manifestations of *Brucella* infection are rare but include iritis, focal nodular choroiditis, and panophthalmitis.²¹⁵

Cat-Scratch Disease

Bartonella henselae is a gram-negative rod transmitted to humans by the bite or scratch of an infected animal, often a young cat or kitten. Regional lymphadenopathy is the predominant nonocular finding. A striking stellate neuroretinitis characterized by swelling of the optic nerves, and lipid deposition in the retina is the most easily identifiable complication of ocular infection. Other manifestations include intermediate uveitis, optic disc swelling, multifocal choroiditis, and serous macular detachment. The discrete foci of multifocal choroiditis are the most common findings in the posterior segment. The role of antibiotics in this condition is debated.^{149,267}

Fungal Uveitis**Histoplasmosis**

The diagnosis of presumed ocular histoplasmosis syndrome is based on the clinical picture of disseminated punched-out retinal lesions, atrophic retinal changes around the optic nerve, and a clear vitreous.²²⁷ Later in the course of the disease, subretinal hemorrhage and retinal detachment may occur. Ocular histoplasmosis often is bilateral and can result in legal blindness from the loss of macular vision. Presumed ocular histoplasmosis syndrome may occur after an episode of benign systemic histoplasmosis during childhood. Active inflammation and vitreous cells usually are not seen in this syndrome, although case series have documented active chorioretinal inflammation as new-onset lesions and as reactivation of previously quiescent lesions.^{42,145} The hallmark histoplasmosis spots appear as white, punched-out, well-demarcated chorioretinal scars and represent healed fungal lesions ("histo spots"). Generally they first appear during adolescence, do not reduce vision, and do not require treatment. Macular disease, which may reduce vision, does not develop until after the patient reaches the second decade of life. Subretinal neovascularization may develop at the site of a macular histoplasmosis spot, with fluid, blood, and lipid accumulating in the subretinal space. This process plus local scarring can result in a marked reduction in central vision.

Macular neovascularization may be treated suitably with laser photocoagulation in an attempt to salvage the remaining central vision. Antifungal drugs may play a role in the unusual setting of demonstrated active histoplasmosis choroiditis.²⁴⁸

Candidiasis

Candida spp., including *Candida albicans*, are fungi with both yeast and filamentous forms. Candidiasis is encountered in immunocompromised patients and in situations involving indwelling catheters, intravenous therapy/drug use, chronic antibiotic use, and poorly controlled diabetes. Candidal chorioretinitis develops in approximately 9% of patients with blood cultures positive for the fungus,⁷⁶ although more recent studies have demonstrated that ocular involvement (either chorioretinitis or endophthalmitis) in children is a rare occurrence.^{77,94}

In the eye, *Candida* infection usually begins in the choroid and eventually causes multifocal white chorioretinal lesions. If the fungus proliferates unchecked, it may break through the retina into the vitreous and produce the classic white snowball-like "fungus ball." Candidal infection that progresses to endophthalmitis is exceedingly rare if appropriate intravenous antifungals are started promptly on notice of a positive blood culture.

Intravenous amphotericin B is the drug of choice. Other antifungal agents such as fluconazole, flucytosine, and miconazole also may be effective but none dramatically so. Surgical treatment of intraocular *Candida* disease is discussed in the section on **endophthalmitis**.

Aspergillosis

Aspergillus spp. can infect the choroid, retina, and vitreous of immunocompromised individuals. One group of investigators found a surprisingly high rate (7%) of these unusual infections on reviewing records of deceased liver transplant recipients.¹³³

Coccidioidomycosis

Coccidioides spp. have both yeast and filamentous forms. Ocular disease consists of a multifocal chorioretinitis that develops during the course of systemic coccidioidomycosis. The lesions initially appear similar to those seen in histoplasmosis; in severe cases, endophthalmitis results, and vitrectomy may need to be performed. In less severe cases, the lesions may respond to intravenous amphotericin B. Occasionally an isolated granulomatous iridocyclitis may develop.¹⁹⁶

Cryptococcosis

Cryptococcus neoformans is a yeastlike fungus that can cause multifocal chorioretinitis and endophthalmitis. Most patients with cryptococcosis are severely immunocompromised, and many have AIDS. The CNS and eye are involved commonly, and elevated intracranial pressure may cause papilledema and sixth cranial nerve palsy. Intravenous amphotericin B in combination with oral flucytosine is the treatment regimen of choice.^{6,150}

Sporotrichosis

The dimorphic fungus *Sporothrix schenckii* is encountered commonly in rotting vegetable matter, wood, and soil. The fungus gains access to the host by traumatic implantation or inhalation. It has been reported to be responsible for anterior uveitis in the setting of a suggestive lesion on a finger of the dominant hand, with presumed hand-to-eye transmission.²⁹⁷

Protozoal Uveitis**Leishmaniasis**

Ocular leishmaniasis has been described but is rare. Manifestations include conjunctivitis, blepharitis, and anterior uveitis. This trio of findings responds to systemic treatment with sodium stibogluconate.⁸⁷

Protozoal Infection

Amebiasis. Humans can be infected by ingestion of the cyst form of *Entamoeba histolytica* in contaminated water and food. The primary disease manifestation in *E. histolytica* infection is dysentery. Ocular involvement is rare and includes maculopathy in the form of a transparent cyst involving the central retina with surrounding retinal hemorrhages and anterior uveitis.^{31,152}

Trypanosomiasis. *Trypanosoma* spp. are flagellated protozoa transmitted by tsetse flies. African trypanosomiasis is caused by *Trypanosoma brucei* and *Trypanosoma cruzi*. General manifestations include headache, fever, malaise, lymphadenopathy, and then CNS involvement with sleepiness, coma, and death. Reported ocular manifestations include urticarial swelling of the eyelids, interstitial keratitis, and rarely, iritis or choroiditis.²³⁹ In American trypanosomiasis, known as *Chagas disease*, intraocular disease has not been reported, but eye involvement may occur in the form of eyelid swelling and periorbital edema spreading to the face.

Malaria. The most serious form of malaria is caused by *Plasmodium falciparum*. Hemolytic anemia and disseminated intravascular coagulation are presumed to lead to hypoxia of the brain and other tissues, resulting in the clinical manifestations of the disease. Ocular manifestations include subconjunctival hemorrhage, retinal hemorrhages, and cranial nerve palsies. Corneal involvement and uveitis are not caused directly by malaria.^{152,168–170}

Giardiasis. Giardiasis is caused by *Giardia lamblia*, which can inhabit the human jejunum. Humans are infected through ingestion of water contaminated with human sewage. Reported ocular manifestations include retinal arteritis (vasculitis) and salt-and-pepper retinal pigmentary changes.^{52,176}

Helminthic Uveitis**Toxocariasis**

Toxocara canis causes visceral larva migrans, which is not associated with ocular disease. In the retina, larvae get trapped in small capillaries and burrow into surrounding tissue; after dying, the dead larvae incite an intense eosinophilic abscess.

Ocular toxocariasis has three classic clinical manifestations, almost always involving one eye only. One form occurs in children 2 to 9 years

of age and causes an indolent endophthalmitis and leukokoria (i.e., white pupil). Tractional retinal detachment may occur. The eye typically shows little or no external evidence of inflammation, and the patient experiences no pain.

A second form appears in children between 4 and 14 years of age. An inflammatory granuloma is seen in the macula. These patients have reduced vision but little or no external inflammation and no pain. The reduced vision may cause strabismus, which may be the first sign.

The third form of ocular toxocariasis occurs in patients between 6 and 40 years of age but may not be recognized until years later. Patients with this form of toxocariasis have good vision, but a peripheral retinal granuloma is seen on routine eye examination. Vision may be affected if a traction band from the granuloma distorts the macula.

Inactive *Toxocara* granulomas do not respond to medication. When active intraocular inflammation exists in such a magnitude that it poses a further threat to vision, administration of periocular or systemic steroids may be necessary. Anthelmintic agents eradicate migrating larvae, but their effect on “residing” larvae is questionable. When giving anthelmintics, one should combine them with a short course of corticosteroids because death of the larvae may incite vigorous inflammation. Cryotherapy and laser therapy may be useful when the *Toxocara* granuloma is located away from the macula and optic nerve. Vitrectomy may be helpful if significant traction on the retina occurs. Anthelmintic drugs should not be administered after the patient has undergone posterior segment surgery. Visual prognosis is poor if the macula is involved.^{215,250,259,307}

Onchocerciasis

Onchocerciasis often causes a severe choroiditis with an overlying retinitis.²⁵⁷ The various ocular manifestations of infestation with *O. volvulus* are discussed in the section on *keratitis*.

Loiasis

The *Loa loa* worm can migrate through the tissues of the eye and cause conjunctivitis, iridocyclitis, vitritis, and chorioretinitis. The disease is transmitted by the bite of the mango fly.⁸³ Vascular obstruction with intraretinal hemorrhage and retinal exudation may occur as well. Medical treatment with diethylcarbamazine can kill the adult worms and microfilariae. Adult worms also can be removed from the eye surgically.²¹⁵

Cysticercosis

The tapeworm *Taenia solium* causes cysticercosis. When the larva gains access to the eye, cysts form in the vitreous or subretinal space in 13% to 46% of patients. The living worm may be seen undulating in these spaces. With death of the organism, severe panuveitis can occur. Orbital and subconjunctival involvement occur less commonly. Surgical removal of the intraocular cysts may prevent the severe inflammation that occurs on the death of the worm. Praziquantel can kill the organism, but the ensuing increase in inflammation may be dramatic.²¹⁵

Rare Causes of Parasitic Posterior Uveitis in Children

Schistosomiasis. Schistosomiasis is caused by a platyhelminth belonging to the trematode class and has three recognized species: *Schistosoma haematobium*, *Schistosoma mansoni*, and *Schistosoma japonicum*. Humans are infected when the larval form emerges from its snail and pierces the skin to enter the dermal lymphatics and capillaries. Reported ocular lesions include generalized cutaneous edema of the eyelids in the acute phase, dacryoadenitis, choroiditis, and rarely retinal pigment epithelium changes.^{74,138,226}

Hydatid disease. Hydatid disease is caused by *Echinococcus granulosus*, for which dogs are the primary host.³⁰⁹ Reported ocular lesions include painless proptosis, subretinal cysts, and rarely involvement of the choroid and the vitreous.^{108,309}

Coenurosis. Coenurosis infection is caused by *Multiceps multiceps*, which is a taenioid cystode. It is a parasite of dogs and related species, with sheep acting as an intermediate host. Humans may occasionally become infected. Reported ocular lesions include conjunctival cysts, intraocular cysts, and subretinal involvement. Panophthalmitis and orbital involvement have been reported.^{175,308}

Ascaris. *Ascaris lumbricoides* is a species of *Ascaris* that infects humans, typically by ingestion of water contaminated with eggs containing infective larvae. Ocular lesions, which are rare, include iridocyclitis and chorioretinitis.¹⁴⁰

Baylisascaris. *Baylisascaris procyonis* may cause ocular disease in humans. This is a nematode of the Ascaridida order, and humans are infected by ingestion of material contaminated with ova.²⁹⁰ *B. procyonis* is a presumptive cause of diffuse unilateral subacute neuroretinitis characterized by unilateral vitritis, papillitis, and recurrent grayish lesions affecting the outer retina and the retinal pigment epithelium.

Gnathostoma spinigerum. *Gnathostoma spinigerum* is a spiruroid nematode endemic in East Asia. The human is an accidental host, and infection occurs by eating infected food. Reported ocular lesions include eyelid swelling, orbital cellulitis, uveitis, intraocular hemorrhage, central retinal artery occlusion, and tractional retinal detachment.^{154,291}

Wuchereria bancrofti. *Wuchereria bancrofti* is prevalent in many tropical areas of the world. Larvae are ingested by species of mosquito feeding on the skin. The larvae then undergo further stages of development and become capable of infecting other individuals when they are released in the saliva of the feeding insect. Reported ocular lesions include conjunctival edema, granulomatous iridocyclitis, and subretinal inflammatory lesions.²⁰⁴

Trichinosis. Trichinosis is caused by *Trichinella spiralis*, a nematode parasite of carnivorous animals of widespread distribution. Human infection results from ingestion of infected, undercooked pork or wild game. Reported ocular lesions include painful limitation of the eye movements associated with proptosis and chemosis, edema of the eyelids and the conjunctiva, and rarely retinal hemorrhages or optic disc edema.^{217,279}

Rickettsial disease. *Rickettsia* are obligate intracellular parasites, possessing both RNA and DNA. Unlike viral infections, they respond to antibiotics. They are transmitted by a vector such as ticks, mites, and fleas. The organisms causing the diseases in the following section have been rarely reported as causing posterior uveitis in humans.⁸²

Typhus. Murine typhus is recognized in scattered pockets worldwide. It is caused by *Rickettsia mooseri* and is transmitted by the rat louse. Ocular manifestations include chorioretinitis, conjunctivitis, and uveitis.

Spotted fever. Boutonneuse fever is recognized in the Mediterranean areas, Caspian and Black sea coastal regions, Africa, Southeast Asia, United States, Russia, and Korea. It is caused by *Rickettsia conorii* and is transmitted by ticks. Ocular manifestations include chorioretinitis, conjunctivitis, and iridocyclitis.

Q fever. Q fever is caused by *Coxiella burnetii*, which is distributed worldwide and is transmitted by ticks. Ocular manifestations include conjunctivitis, episcleritis, uveitis, and chorioretinitis.

Trench fever. Trench fever is caused by *Rochalimaea quintana* and is transmitted by the human body louse. Ocular manifestations include retinitis and conjunctivitis.

Uveitis Caused by Insect-Induced Disease

Ophthalmomyiasis is an ocular disorder caused by infestation with fly larvae, most commonly the larval form of the sheep botfly *Oestrus ovis*. Maggots may be seen in the conjunctival fornix or inside the eye. Internal ophthalmomyiasis can be diagnosed by noting a motile larva in the anterior chamber, vitreous, or subretinal space. The maggot may leave trails (“railroad tracks”) throughout the retina. A mild inflammatory response in the anterior chamber or vitreous may occur. Treatment is surgical removal of the larva. Corticosteroids may be used to treat the accompanying intraocular inflammation.^{84,215}

Postinfectious Uveitis

Increasingly, attention is being given to the role of bacterial and viral systemic illness in the eventual development of sterile intraocular inflammation. This type of uveitis is thought to be caused by an autoimmune response that occurs between sensitized lymphocytes and host tissues that bear some antigenic similarity to the recently cleared pathogen. Disruption of the ACAID is probably a prerequisite for the development of these postinfectious syndromes. Several reports exist of nongranulomatous anterior uveitis occurring weeks or months after streptococcal infection. These uveitides may be associated with other

poststreptococcal findings (e.g., arthritis and glomerulonephritis) or may be the sole manifestation. Treatment with cycloplegics and topical corticosteroids is sufficient for the ocular manifestations.^{19,292,311}

Uveitis, predominantly of the anterior type, has been reported to occur after illnesses caused by gram-negative enteric bacteria such as *Klebsiella*, *Salmonella*, and *Yersinia*. These gram-negative-induced uveitides are much more likely to occur in the setting of human leukocyte antigen (HLA)-B27 positivity. The ocular findings often parallel the development of arthritis, thus suggesting that parallel immunologic processes are occurring in both these mesenchymal cavities (i.e., the joint space and the anterior chamber). An association between recent EBV infection and acute tubulointerstitial nephritis and anterior uveitis has been described, with onset of the renal and ocular inflammation occurring several months after the characteristic acute EBV infection.¹¹²

INFECTIONS INVOLVING PRIMARILY THE RETINA

Eye Manifestations of Intrauterine Infections (TORCHES Complex)

The TORCHES complex is a group of congenital and perinatal infections that may cause severe systemic and ophthalmic abnormalities. The effect of infection with one of the TORCHES organisms—*Toxoplasma gondii*, others (LCMV, parvovirus B19), rubella virus, CMV, herpesvirus, EBV, and syphilis—may be evident at birth or manifest later in childhood or adulthood. All of these infections commonly cause either mild or no clinically evident disease in the mother.¹⁸⁸ The diagnosis cannot always be established on clinical grounds alone, and neonatal and maternal serologic tests must be performed to confirm the clinical suspicion.

Toxoplasmosis

T. gondii is an obligate intracellular parasite that has an affinity for the CNS and retina. The parasite has three forms: tachyzoite, bradyzoite, and sporozoite or oocyst. Human infection may be congenital or acquired. Acquired infection results from the ingestion of undercooked meat contaminated with oocysts or from exposure to the feces of an infected cat, the definitive host. The oocysts release tachyzoites, which multiply intracellularly and result in cell death. In adults, primary acquired infection usually is asymptomatic. The immune response then transforms the tachyzoite into a bradyzoite, which encysts and remains dormant in tissues for years. These cysts have the propensity to rupture sometime later and cause an inflammatory response resulting in recurrent infection.

Congenital infection is transmitted transplacentally. In the United States, the reported incidence of congenital toxoplasmosis is one case per 1000 to 10,000 births.^{12,57} As much as 70% of the obstetric population is negative for antibodies and therefore at risk for infection and transplacental transmission to the fetus.¹⁸⁸ Congenital infection is most severe when acquired in the first trimester and can result in chorioretinitis, intracranial calcifications, microcephaly, mental retardation, and deafness.^{57,90,92} Symptomatic neonates with disseminated disease have hepatosplenomegaly, lymphadenopathy, jaundice, fever, anemia, pneumonitis, and a poor prognosis. Other ocular manifestations include cataracts, strabismus, microcornea, vitreitis, retinal detachment, optic atrophy, microphthalmos, nystagmus, and ptosis.¹⁸⁸ In a prospective study, 15% of infected newborns had chorioretinal scars, indicative of infection in utero; 4% had active chorioretinitis; and in 10%, retinal lesions developed by the time the children were 1 to 2 years of age. Long-term follow-up studies found that chorioretinal lesions develop in 82% to 85% of children with subclinical *Toxoplasma* infection, some with severe visual loss. Infants with asymptomatic toxoplasmosis should undergo regular ophthalmologic examination because retinal involvement can occur later in childhood and adulthood.^{32,92,155} Some researchers suggest that all neonates with toxoplasmosis should receive drug therapy, even if they are asymptomatic.⁹²

Toxoplasmosis is the leading cause of acquired necrotizing retinitis and, in many cases, represents reactivation of congenitally acquired infection. Clinically, the area of active retinochoroiditis is adjacent to the border of a chorioretinal scar.^{92,236} Associated choroiditis and vitreitis,

sometimes severe, may be present. Primary acquired ocular toxoplasmosis manifested as retinochoroiditis is well documented also, and reports suggest that this route of infection may be more common than originally thought.^{32,130} Recurrent ocular disease with postnatally acquired toxoplasmosis has been reported.²⁹

T. gondii causes a focal necrotizing retinitis with secondary choroiditis and vitreitis. Patients may have floaters, blurred vision, and photophobia. Those with macular involvement can suffer significant visual loss. After the inflammation has resolved, a flat, pigmented chorioretinal scar develops. Visual loss depends on the location of the retinal lesion, with peripheral lesions resulting in little or no visual disturbance and macular lesions capable of producing profound visual loss.

Toxoplasma retinochoroiditis is an emerging problem in patients with AIDS and may be the initial manifestation of this syndrome.³⁰³ The clinical appearance often is atypical.²⁶⁴ Chronic suppressive therapy is necessary because infection recurs with discontinuation of treatment. A combination of pyrimethamine and clindamycin has been reported to be most effective as prophylaxis.³⁰³

The diagnosis of *Toxoplasma* retinochoroiditis usually is presumptive and is based on clinical appearance and serologic testing. Several serologic tests are available. The standard serologic diagnosis is based on the presence of anti-*Toxoplasma* IgM in any sample or demonstration of a significant rise in antibody titer in paired sera taken 4 to 6 weeks apart. However, in reactivated congenital infections, which many cases are, *Toxoplasma* IgM results are not positive. The antibody tests most commonly used are indirect immunofluorescent assay (IFA) and enzyme-linked immunosorbent assay for IgM and IgA.¹⁰⁶ False-positive results can occur with both tests in the presence of rheumatoid factor. If clinical infection is suspected and the initial testing results are negative, repeat testing or an alternative testing technique should be considered.

Standard treatment of *Toxoplasma* retinochoroiditis is triple therapy with sulfadiazine 100 to 200 mg/kg per day in four divided doses (maximum, 1.5 g), pyrimethamine 2 mg/kg per day for 3 days, then 1 mg/kg per day (maximum, 25 mg/day), and leucovorin (folinic acid) 10 to 25 mg given orally daily for 6 weeks. Folinic acid prevents the leukopenia and thrombocytopenia that may result from pyrimethamine therapy. Weekly complete blood counts and platelet counts are required to monitor toxicity from therapy. Alternative therapy with clindamycin 40 mg/kg per day in four divided doses (maximum, 2.4 g for 6 weeks) rather than sulfadiazine also has been effective.²⁸² This therapy is less toxic than triple therapy and is therefore better tolerated. In patients with severe intraocular inflammation, systemic corticosteroids can be used with concurrent antimicrobial therapy.

Preventive measures are twofold: first, avoidance of raw meat and cat feces during pregnancy, especially during the first trimester, and second, treatment of a mother known to have contracted the disease during pregnancy with spiramycin, because it has no known teratogenic effects.^{55,68,69} In utero pyrimethamine and sulfadiazine treatment of a fetus known to be infected may be effective.^{55,57,127}

Lymphocytic Choriomeningitis Infection

LCMV, an arenavirus discovered in 1933, was first recognized as a cause of intrauterine infection in 1955 (also see the earlier section on viral uveitis).¹⁸⁹ The common house mouse *Mus musculus* is the natural host and reservoir of the virus, but laboratory mice and pet hamsters also may be infected.^{8,126} LCMV may be transmitted to humans by airborne means, rodent bites, or food contaminated by rodent urine, feces, or saliva; the fetus may be infected by transplacental transmission.¹⁰⁶ The diagnosis may be confirmed by LCMV titers.

Systemic manifestations, often devastating, include hydrocephaly, microcephaly, periventricular calcifications, neonatal meningitis, hepatosplenomegaly, cerebral palsy, mental retardation, and seizures.¹⁰⁶ Ocular findings include chorioretinitis, optic atrophy, nystagmus, microphthalmos, strabismus, and cataracts.¹⁸⁹ The chorioretinitis may mimic congenital toxoplasmosis.³³ The most common ocular findings are peripheral chorioretinal scars, although macular involvement is a common occurrence as well. At present there is no effective treatment. Prevention involves avoidance of mice and hamsters by pregnant women.^{106,189}

Rubella Infection

The rubella virion is an RNA virus of the family *Togaviridae* that causes a febrile exanthem. Before the advent of rubella vaccine in 1969, rubella, or German measles, epidemics occurred every 6 to 9 years. The last major outbreak in the United States took place in 1964.¹⁴ With preschool immunization programs, most primary cases now reported occur in individuals between 15 and 24 years of age. Transmission occurs by inhalation of aerosolized droplets in the nasopharynx. Primary infection in adults results in a mild febrile illness associated with lymphadenopathy and a rash. The proportion of susceptible nonimmunized women of child-bearing age ranges from 10% to 25%. Fetal infection occurs transplacentally, and the likelihood of transmission from mother to fetus is highest (90%) in the first trimester; transmission at this stage can produce severe fetal damage and result in spontaneous abortion, stillbirth, or multiple congenital anomalies.

The classic congenital rubella syndrome, first described by Sir Norman McAlister in Australia in 1949,¹⁸⁹ is characterized by cardiac defects, ocular abnormalities, and hearing deficits. The incidence of ocular and cardiac defects is higher with exposure early in the first trimester; hearing deficits appear to be associated with exposure late in the first trimester. Givens et al.¹⁰⁵ reported that 88% had multiorgan involvement. Hearing loss is the most frequent nonocular manifestation.¹⁸⁹ The most common cardiac defects are patent ductus arteriosus, pulmonary artery stenosis, and pulmonary valve stenosis. Other features include microcephaly, thrombocytopenia, hepatosplenomegaly, and mental retardation.

Ocular involvement occurs in approximately 50% of infected infants.¹⁰² Pigmentary retinopathy (i.e., “salt-and-pepper” retinopathy) affects 22% of infected infants. The retina has a mottled appearance, most frequently observed in the posterior pole; the optic nerve and vessels usually are normal unless the patient also has glaucoma.

Nuclear cataracts, which affect between 15% and 27% of patients, are the second most frequent ocular complication. Glaucoma is seen in approximately 10% of eyes; the combination of cataracts and glaucoma is an uncommon finding.³⁰⁰ Microphthalmos (which occurs in 10% to 63% of affected individuals), iris atrophy, and iritis also have been reported.²⁷ Live virus may persist for years in the lens, so appropriate precautions must be taken during cataract surgery to prevent transmission.¹⁰⁶

The retinopathy associated with rubella usually is asymptomatic and does not necessitate treatment. In some cases, it can be complicated by subretinal neovascularization, which may require laser or macular surgery. Cataracts cause most visual morbidity. Visual rehabilitation depends on early cataract extraction to prevent deprivation amblyopia, correction of aphakia with spectacles or contact lenses, and careful follow-up. Glaucoma in infants and children can be temporized with topical medications, but most cases require glaucoma surgery.

Congenital rubella has long-term consequences for all organs involved. In nearly two thirds of infants with no manifestations at birth, hearing loss or psychomotor deficits subsequently develop. From an ophthalmic standpoint, individuals with congenital rubella need continued follow-up.¹⁰⁵

Cytomegalovirus Infection

CMV is an enveloped DNA virus of the family *Herpesviridae*. An estimated 80% of adults are infected by the time they reach 40 years of age.²⁶⁹ In immunocompetent adults, infection is asymptomatic or can cause a mononucleosis-like syndrome. Individuals can shed virus in saliva, urine, and other body fluids for months to years after initial infection. Transmission occurs through exposure to body fluids (sexual contact, blood transfusion) or organ transplantation, or it can occur transplacentally. Primary infection acquired in the birth canal is not likely to result in serious disease.

Congenital CMV is the most common congenital infection in humans²⁷⁰ and can result from exposure to the virus in utero or in the birth canal. In utero infection produces more serious disease. CMV infection occurs in 1% of all live births, and only 5% to 10% of infants with congenital CMV infection are symptomatic. Maternal infection may be primary or recurrent, but primary infection carries the greatest risk (30% to 40%) for transmission of symptomatic CMV disease to the newborn.²⁶⁹ Blood transfusions from CMV antibody-positive donors

also can result in severe CMV infection in the newborn. Systemic manifestations include intrauterine growth restriction (IUGR), thrombocytopenic purpura, microcephaly with periventricular calcifications, hepatosplenomegaly, pneumonia, and sensorineural deafness.⁶⁵ In symptomatic congenital CMV infection, the retina is the primary site of ocular involvement. Cytomegalic inclusion bodies are seen in all layers of the retina. Patchy white areas of necrotic retina with hemorrhage and vascular sheathing are seen in the peripheral portion of the retina, although the posterior pole can be affected as well.¹⁶⁷ Nonhemorrhagic retinitis also may be seen, and most affected infants do not have active retinitis at birth, although scars may be visible as evidence of previous disease.⁵⁰ Resolution of the retinitis results in an atrophic scar with areas of hyperpigmentation. If retinitis is limited to the retinal periphery, vision may be normal. However, visual loss may occur if the posterior pole is involved or if optic atrophy or retinal detachment occurs. CMV retinopathy develops in 5% to 30% of infants with clinically apparent disease.⁸⁵ Microphthalmos, optic nerve hypoplasia, optic atrophy, optic nerve colobomata, anophthalmia, corneal opacities, and anterior segment dysgenesis also have been associated with congenital CMV infection.¹²⁸ In addition, cyclopia and anophthalmia have been reported.¹⁶⁷

The diagnosis of CMV retinitis is based on the clinical appearance and the constellation of systemic symptoms and signs. Recovery of the virus from urine, maternal cervical secretions, saliva, or aqueous humor can confirm the diagnosis. Complement fixation can identify IgM antibodies to CMV that do not cross-react with other herpes viruses. Immunofluorescence techniques are more sensitive but less specific than complement fixation.¹⁶⁷

Treatment of neonatal or pediatric CMV retinitis is based on the results of treatment of adults with CMV retinitis. Ganciclovir has been shown to stabilize and prevent spread of the disease in infants. Maintenance therapy is not required, but continued follow-up is necessary to detect recurrence. Leukopenia and thrombocytopenia can result. Retinal detachment requires vitrectomy, membrane peel, and silicone oil to tamponade the detached retina.^{39,129}

Herpes Simplex Virus Infection

HSV is a double-stranded, enveloped DNA virus. Both subtypes, HSV-1 and HSV-2, can cause a vesicular skin eruption. HSV-1 typically is isolated from oral-facial infections; HSV-2 usually is isolated from genital infections. After primary infection occurs, HSV can maintain latency in neuronal ganglion cells and reactivate. Transmission occurs by exposure to infected body fluids such as saliva, and the risk for transmission is higher when the individual is symptomatic.²⁰¹

Maternal-fetal transmission occurs through infected genital secretions in the birth canal (HSV-2) or exposure to infected individuals with oral-facial herpetic disease (HSV-1) in the postnatal period. In mothers with active genital disease, the risk for transmission to the neonate is 50% with vaginal delivery. Most series report that between 70% and 80% of neonatal HSV infection is caused by HSV-2. Neonatal HSV infection is life-threatening, and the mortality rate without treatment is 50% to 80%.^{106,305} The diagnosis is suspected by the clinical findings—lethargy, respiratory distress, anorexia, vomiting, cyanosis, low birth weight, IUGR, microcephaly, seizures, intracranial calcifications, pneumonia, hepatosplenomegaly, and skin vesicles. The virus may be isolated from skin vesicles or from nasal or conjunctival secretions, CSF, or blood.

Ocular sequelae develop in fewer than 1% of immunocompetent adults with HSV infection. In contrast, 17% to 40% of infected neonates have ocular disease.^{181,269} Thirteen percent of neonates with HSV have eye involvement. Ocular involvement can range from mild conjunctivitis to severe bilateral necrotizing retinitis and may be unilateral or bilateral. Conjunctivitis is the most common manifestation. Conjunctivitis, keratitis, and, occasionally, retinitis develop 2 to 14 days after birth. HSV retinitis causes punctate, white-yellow lesions in the periphery and the posterior pole accompanied by choroiditis, vascular sheathing, hemorrhage, and vitritis. Chorioretinal atrophic scars with variable amounts of pigmentation around the border result after resolution of acute infection.^{131,231} Visual prognosis depends on the severity of disease, presence of macular involvement, extent of optic atrophy, or CNS involvement of the visual pathways. Severe chorioretinitis and cortical

blindness are the usual sequelae of HSV infection acquired through transplantation, a rare mode of transmission.

El Azazi et al.⁸⁶ examined children with serologically proven HSV infection 1 to 15 years after neonatal exposure and found a higher prevalence of chorioretinal scars than noted in previous reports (28% vs. 4%). This finding suggests that HSV remains dormant in the retina and reactivates later in childhood or adulthood. Chorioretinitis, cataracts, optic atrophy, and microphthalmos have all been reported.¹¹⁶ Acute retinal necrosis from reactivation of HSV-2 has occurred as well.²⁸⁵

Ocular HSV infection can be seen in conjunction with a vesicular rash or disseminated disease. The differential diagnosis of ophthalmic complications from HSV includes infection with any of the TORCHES organisms. Identification of neonatal IgM antibody to HSV confirms the diagnosis of in utero infection. Demonstration of intranuclear inclusions and multinucleated giant cells in skin, conjunctiva, and oral and genital lesions may be diagnostic.

The drug of choice to treat neonatal HSV infection is intravenous acyclovir 60 mg/kg per day.²²³ Conjunctival and corneal disease also can be treated by debridement and topical antivirals such as trifluridine drops or ganciclovir ointment. In neonatal HSV infection, systemic acyclovir should be given regardless of topical treatment. Early diagnosis and treatment can reduce ocular morbidity.

Varicella-Zoster Virus Infection

Varicella zoster is a DNA virus of the family Herpesviridae; enveloped virions are the infectious agents. Primary infection results in chickenpox, a highly communicable febrile illness with a vesicular rash that appears after 48 to 72 hours of incubation. VZV can remain dormant in sensory ganglion neurons and reactivate as herpes zoster, a painful rash in the dermatomal distribution of the sensory ganglion.

Congenital varicella syndrome is considered a rare entity, though one prospective series reported a 24% incidence of congenital varicella with serologic or clinical confirmation of maternal infection during pregnancy. Mortality rates can be high if maternal infection develops anywhere from 5 days before delivery to 2 days after delivery. Systemic complications of VZV infection include cranial nerve palsy, hemiparesis, cicatricial skin lesions, IUGR, developmental delay, seizures, neurogenic bladder, and learning difficulty.^{156,219}

Ocular abnormalities in children with congenital VZV infection include chorioretinitis, cataracts, Horner syndrome, optic atrophy/optic nerve hypoplasia, retinal coloboma, and microphthalmos. The chorioretinal scars of VZV infection have a deeply pigmented center with depigmented borders or a gliotic white center with hyperpigmented edges. The neurotropic nature of VZV infection may explain the association of Horner syndrome. Ocular involvement can be unilateral or bilateral. VZV chorioretinitis affects the macula, periphery, or both.

Serologic testing for IgG and IgM antibodies to VZV, a history of maternal infection during pregnancy, and the constellation of systemic findings helps establish the diagnosis. Because active infection may occur early in pregnancy, the neonate may have IgG but no detectable IgM antibodies to VZV by the time of delivery. The persistence of elevated IgG antibodies beyond 6 months (when passive immunity through maternal antibodies has waned) without evidence of postnatal primary VZV infection is a helpful indication of infection in utero.

Syphilis

Syphilis is caused by the spirochete *Treponema pallidum*. Acquired syphilis is a sexually transmitted chronic disease and has three stages of infection. Primary infection is characterized by painless, indurated chancres of the skin or mucous membranes at the site of inoculation. The secondary stage appears as a maculopapular rash, classically involving the palms and soles. Generalized lymphadenopathy, fever, malaise, sore throat, headache, and arthralgias can accompany the rash. Hypertrophic lesions (i.e., condyloma lata) occur in moist mucous membranes. Approximately a third of untreated cases progress to the tertiary stage, which occurs after a variable latent period that may have occasional recurrences of secondary syphilis. Transmission to the fetus can occur with any stage of maternal syphilis.²⁸⁰

Pigmentary retinopathy is the most common early ocular manifestation of congenital syphilis. Diffuse mottling in the periphery

(“salt-and-pepper” retinopathy) is indicative of in utero infection. Pigment clumping in the periphery usually has no effect on vision, but macular involvement can cause decreased vision. Retinal changes can appear later in adulthood, thus suggesting that inflammatory changes caused by congenital infection can occur after birth. Salt-and-pepper retinopathy is evidence of previous inflammation, and no treatment is required. Interstitial keratitis (see the previous discussion of [stromal keratitis](#)) is the hallmark of congenital syphilis and occurs in 75% of these patients.²⁸⁰ It is usually not detected until late in the first decade of life. Other reported ocular manifestations include optic neuritis and iritis.

Testing the serum by nontreponemal and treponemal methods confirms the diagnosis of congenital infection. The American Academy of Pediatrics recommends physical examination, quantitative nontreponemal serologic testing, a CSF Venereal Disease Research Laboratory (VDRL) test, long-bone radiographs, and antitreponemal IgM testing, as specified by the Centers for Disease Control and Prevention (CDC). The CDC states that congenital syphilis is presumptively diagnosed with a positive VDRL and at least one of the following: physical examination evidence of congenital syphilis, characteristic radiographic long-bone findings, VDRL-positive CSF findings, an otherwise unexplained elevated CSF protein or cell count, quantitative nontreponemal serologic titer four times greater than the mother's, or a positive fluorescent treponemal antibody absorbent FTA (ABS) 19s IgM test.⁵ Treatment is with intravenous penicillin G for 10 to 14 days.^{6,177}

Endophthalmitis

Endophthalmitis is an infection within the eye that may arise endogenously during septicemia or exogenously from accidental or surgical trauma.^{191,202} Sixty-two percent of cases occur after intraocular surgery, 20% after penetrating trauma, 10% after glaucoma surgery, and 8% result from endogenous infection.^{76,229} The patient usually has severe ocular pain and visual loss at initial evaluation. Rarely patients may be asymptomatic. Signs of endophthalmitis include conjunctival injection, vitritis, uveitis, hypopyon, and intraocular membrane formation.

Endophthalmitis is an ophthalmic emergency and necessitates immediate evaluation of aqueous and vitreous cultures and institution of intravitreal antibiotic therapy. Any significant delay in recognition and treatment of endophthalmitis can result in permanent vision loss. Vitrectomy is indicated in those patients with near-total blindness.^{6,88}

Postsurgical endophthalmitis occurs in 0.086% of cataract operations.² The source of postsurgical infection may be from the eyelids, conjunctiva, contaminated instruments/irrigating solutions, or contamination by operating room personnel. The routine use of subconjunctival antibiotics after intraocular surgery does not prevent all cases of postoperative endophthalmitis. Vitreous loss, which may occur occasionally as a complication of cataract surgery, increases the risk for infection developing. Patients who have undergone glaucoma filtering surgery are particularly prone to endophthalmitis, primarily because sclerostomy is performed routinely as part of this procedure, and the only remaining protection the eye has from infective organisms is a thin layer of conjunctiva overlying the sclerostomy. Local antimetabolites, often used in conjunction with glaucoma filtering procedures, predispose the conjunctiva to bleb leaks that allow direct access of microorganisms to the eye.

Endogenous (metastatic) endophthalmitis should be suspected when ocular inflammation occurs in a septicemic patient, particularly if the patient is immunocompromised or has an underlying systemic illness such as diabetes or leukemia.^{28,199,213}

Posttraumatic endophthalmitis should be considered in any patient with a history of injury and visual loss. A history of a high-velocity projectile presents great concern for a penetrating injury, and apparently minor accidental ocular trauma may result in perforation of the globe with or without a retained foreign body. The likelihood of posttraumatic endophthalmitis increases directly with the extent of the injury and the degree of intraocular contamination.

After the diagnosis is suspected, immediate referral to an ophthalmologist is imperative. Once the patient has been examined, a vitreous and aqueous aspirate is obtained under general anesthesia and material is evaluated with Gram and Giemsa stains. Staining with calcofluor white

or acridine orange is performed if fungal infection is a concern. The material is cultured on blood and chocolate agar, thioglycolate broth, and Sabouraud agar. Vancomycin 1 mg to cover gram-positive organisms and ceftazidime 2.25 mg to cover gram-negative organisms are injected into the vitreous cavity. If fungal infection is suspected, intravitreal amphotericin B is given. Occasionally the ophthalmologist uses intravitreal dexamethasone to control associated, intense intraocular inflammation. Gram stain results often are inconsistent with cultures.

The role of vitrectomy in postoperative endophthalmitis has been addressed in the Endophthalmitis Vitrectomy Study (EVS).^{6,88} In eyes with better than light perception vision at initial evaluation, outcome measurements were equal between the vitrectomy group and the vitreous tap or biopsy group. In eyes with light perception vision or worse, the EVS found that patients who underwent immediate pars plana vitrectomy did significantly better than those who underwent vitreous tap or biopsy alone.

The most common infectious agents in endophthalmitis are *S. epidermidis*, *Bacillus* spp., *Streptococcus* spp., *S. aureus*, and various fungi. *Bacillus cereus* is isolated in 30% to 40% of cases and can cause severe ocular morbidity.^{1,61,62,73,123} *S. epidermidis* is the predominant organism in postoperative cases, and *Streptococcus* spp. with filtering blebs and *B. cereus* are the organisms associated most frequently with penetrating trauma. Approximately 65% of cases are culture positive.

Fungal endophthalmitis has become a relatively common form of endophthalmitis in childhood because of the prolonged hospital care required for severely ill immunocompromised children. The most common organism is *C. albicans*. Children with a central line catheter or receiving prolonged intravenous therapy of any type are particularly prone to infection. In patients with *Candida* endophthalmitis, the vitreous may be hazy, and small, white “snowball” localizations of infected material may appear in the vitreous or on the surface of the retina. Daily careful observation may be required during intravenous amphotericin B therapy. If the endophthalmitis clears, no ocular surgical intervention is indicated. If the infection is not adequately controlled with intravenous therapy, vitrectomy with injection of intravitreal amphotericin may be required.⁸⁸

Bacteremia and Septic Shock

Sheldon L. Kaplan • Jesus G. Vallejo

One of the most serious and potentially life-threatening infectious diseases in childhood is a bacteremic illness. Bacteremia may be caused by a wide variety of gram-positive or gram-negative microorganisms, and it may or may not be associated with a specific focus of infection, such as pneumonia or meningitis. Some bacteremias are transient and self-limited; they are not discussed in this chapter.

The incidence of bacteremia in children has been studied in hospital and ambulatory settings. In otherwise normal children, beyond the newborn age group, *Streptococcus pneumoniae*, *Escherichia coli*, *Staphylococcus aureus*, group A streptococcus, *Salmonella* spp., and *Neisseria meningitidis* are the most common microorganisms causing bacteremia.^{92,230} The incidence of pneumococcal bacteremia has decreased substantially since the introduction of the conjugate pneumococcal vaccine.^{116,165} In contrast, methicillin-resistant *S. aureus* bacteremia has increased in children in the United States since 2000.⁷⁷ Children with underlying illnesses that depress the host response to infection may develop bacteremia caused by these same microorganisms; however, in this population of children, especially when hospitalized, Enterobacteriaceae, *S. aureus*, coagulase-negative staphylococci, and fungi are the most important organisms commonly isolated from blood cultures.^{5,158} Indwelling vascular lines, urinary catheters, endotracheal tubes, and other foreign material further predispose already compromised children to nosocomial infections. The incidence of diagnosed septicemia has increased over the years, partly owing to improved medical technology and the greater numbers of individuals with immunocompromising conditions who previously would not have survived.¹⁹⁵

Gray and colleagues⁸⁵ reported that the incidence of bloodstream infections in a pediatric intensive care unit (ICU) during a 3-year period was 39 cases per 1000 admissions. Of the episodes, 64% were acquired in the ICU and 20.6% were community-acquired infections. Gram-positive and gram-negative organisms accounted for 62% and 31% of the isolates. Yeasts were isolated in 5.6% of episodes. The frequency of catheter-related bloodstream infections has been decreasing in many PICUs as a result of implementing insertion and maintenance bundles.¹³⁵ Children with acquired immunodeficiency syndrome or severe immunosuppression caused by human immunodeficiency virus infection also are at increased risk for developing bacteremias caused by gram-negative bacilli, especially *Pseudomonas aeruginosa*.¹⁷⁷

Using a seven-state hospital discharge database, Watson and associates²³⁰ estimated that the U.S. age-adjusted and sex-adjusted annual incidence of severe sepsis was 0.56 cases per 1000 children, or more than 42,000 cases per year. The highest age-specific incidence occurred in infants (5.16 cases per 1000), declining to 0.20 cases per 1000 for children 10 to 14 years old. Half of the children had underlying comorbidity, with neuromuscular, cardiovascular, and respiratory disorders being the most common.

One potential consequence of bacteremia is septic shock, a state characterized by inadequate tissue perfusion that is associated frequently with endotoxemia. Although most children with septic shock have infections caused by gram-negative enteric bacteria, *P. aeruginosa*, or *N. meningitidis*, organisms with endotoxin or lipopolysaccharide (LPS) within cell walls, septic shock also is associated with disease caused by gram-positive bacteria (especially *S. aureus*, *Streptococcus pyogenes*, and viridans streptococci), viruses, rickettsiae, and fungi. Community-acquired methicillin-resistant *S. aureus* (MRSA) in particular have been associated with severe sepsis and septic shock in young children and adolescents.^{4,82} In adults, the frequency of septic shock continues to increase as the population ages, new technology including more

complicated surgery and immunosuppressive agents is developed, and antibiotic resistance grows.¹⁸⁰

In early studies of septic shock, Dupont and Spink⁵⁹ reviewed the cases of 172 children, age 30 days to 16 years, who were hospitalized at the University of Minnesota Medical Center with gram-negative bacteremia. Shock occurred in 25% of the children, and 98% of children with shock died. In meningococcal infections, 11% to 40% of children develop hypotension.^{105,225} During a 10-month study period, Naqvi and colleagues¹⁴⁶ reported that shock occurred in five of 39 (13%) episodes of gram-negative bacillary sepsis, with three deaths. Jacobs and associates⁹⁸ reviewed the admissions of previously normal children to a pediatric ICU in a large children's hospital for a 30-month period. Hypotension or evidence of peripheral hypoperfusion occurred in 143 children with confirmed bacterial sepsis, mostly *Haemophilus influenzae* type b (Hib), or apparent meningococcemia. Among 1058 consecutive admissions of 916 children to a pediatric ICU in Canada from July 1, 1991, to July 31, 1992, 25 episodes (2%) of septic shock occurred.¹⁶⁷ During a 12-month period, 140 episodes of septicemia (135 bacterial and five fungal) were documented in 100 pediatric hematology-oncology patients.⁶⁷ Septic shock occurred in 19%.

The organisms and case-fatality rates in the study by Watson and colleagues²³⁰ are outlined in Table 62.1. *N. meningitidis* and fungi were associated with the highest mortality rates. Early-onset group B streptococcal infections in neonates and overwhelming *S. pneumoniae* infections in children with splenic dysfunction or asplenia are associated with shock in a high percentage of cases. *S. aureus* or group A streptococcus may cause hypotension in a child with or without other manifestations of toxic shock syndrome.¹⁸⁹

Using data from the Pediatric Health Information System database (2004–12; 43 hospitals), Ruth and associates¹⁸¹ estimated an overall prevalence of pediatric severe sepsis of 7.7% with an associated mortality of 14.4%. Mortality was highest in patients with malignancies (22.4%), hematologic or immunologic disorders (20.3%), and cardiovascular disease (20%). The most common sites of infection were bloodstream (67.8%), respiratory tract (57.2%), and genitourinary tract (21.6%). *Staphylococcus* spp. (9.9%) and *Streptococcus* spp. (5.4%) were the most common causative agents, with fungi accounting for less than 1% of isolates. In patients in whom a bacterial pathogen was identified, the reported mortality rate was 13.2%. Although fungal infections as a cause of pediatric severe sepsis was rare, mortality in this group was high (20.1%) when compared to the overall mortality rate (14.4%).

Weiss et al.²³⁶ described the global epidemiology of pediatric severe sepsis at 128 sites in 26 countries. The sites included 59 in North America, 39 in Europe, 10 in South America, 10 in Asia, 7 in Australia/New Zealand, and 3 in Africa. The overall point prevalence of pediatric severe sepsis was 8.2%. Point prevalence was highest in Asia (15.3%), South America (16.3%), and Africa (23.1%). The most common sites of infection were the respiratory tract (40%) and the bloodstream (19%). The proportion of infections caused by gram-positive and gram-negative organisms was similar (26.5% vs. 27.9%), with *S. aureus* accounting for most of the bacterial isolates (11.5%). Overall hospital mortality was 25% but varied across geographic regions (North America 21%, Europe 29%, Australia/New Zealand 32%, Asia 40%, and South America 11%).

Advances in understanding of the pathogenesis and pathophysiology of septic shock with respect to the host response to infection have required that more precise clinical definitions of sepsis and expanded syndromes be developed. Much of the impetus for this effort is related

TABLE 62.1 Occurrence and Case-Fatality Rates of Selected Pathogens Among Children With Severe Sepsis Based on Age^a

Organism	<1 Y (N = 4643)		1–10 Y (N = 2724)		11–19 Y (N = 2308)	
	Cases (%)	Case Fatality (%)	Cases (%)	Case Fatality (%)	Cases (%)	Case Fatality (%)
<i>Neisseria meningitidis</i>	0.3	20	8	10.4	2.3	15.1
<i>Haemophilus influenzae</i>	1.6	4.2	2.4	1.6	1.9	6.8
<i>Pseudomonas</i>	3.6	14.6	7.7	12.4	6.9	9.4
<i>Staphylococcus aureus</i>	2.3	5.7	2.9	0	3.5	3.8
Group A streptococcus	0.3	0	0.7	5	0.2	0
Group B streptococcus	3.1	7.6	0.1	50	0.8	5.6
Fungus	10	10.8	13.3	16.8	10.4	11.6

^aRepresents data from a seven-state hospital discharge database in 1995.

Modified from Watson RS, Carcillo JA, Linde-Zwirble WT, et al. The epidemiology of severe sepsis in children in the United States. *Am J Respir Care Med.* 2003;167:695–701.

to the ability to more readily identify patients with infections who may benefit from administration of newer (expensive) adjunctive measures. An American College of Chest Physicians and Society of Critical Care Medicine Consensus Conference in 1991 developed new terminology to define sepsis and its sequelae.²⁴ This terminology has been modified for use in children by an international consensus panel of 20 experts in sepsis and clinical research (Box 62.1).⁸⁰

In 2016, a 19-member joint task force of the Society of Critical Care Medicine and European Society of Intensive Care Medicine (ESICM) published new sepsis guidelines for adult patients.¹⁹⁰ According to the new guidelines, sepsis is now defined as evidence of infection plus life-threatening organ dysfunction. Organ dysfunction will be characterized clinically by a change of 2 points or greater in the Sequential (sepsis-related) Organ Failure Assessment score (SOFA). Given that SOFA is based on laboratory tests, the new guidelines recommend that clinicians use a streamlined process called quick SOFA (qSOFA) to assess patients for sepsis outside the intensive care unit.¹⁸⁵ The clinician will assess a patient for altered mental status, systolic blood pressure of 100 mm Hg or lower, and a respiratory rate of 22 breaths per minute or higher. Patients meeting two of the qSOFA criteria will require close monitoring.

The 2016 clinical criteria for septic shock in adults include sepsis with fluid-unresponsive hypotension, serum lactate level of greater than 2 mmol/L, and need for vasopressors to maintain a mean arterial pressure of 65 mm Hg or higher.¹⁸⁶ The 2016 consensus definition eliminates the use of the term systemic inflammatory response syndrome (SIRS). It should be noted that the utility of these definitions among pediatric populations is still to be determined.

PATHOPHYSIOLOGY

The pathophysiology of bacteremia is highly variable and depends on the specific microorganism isolated, the immune status of the host, and other factors such as the locations of indwelling catheters. Highly encapsulated organisms, such as *S. pneumoniae*, *N. meningitidis*, and Hib, normally may reside in the nasopharynx and, for reasons that are poorly understood, are capable of invading beyond mucosal barriers into the bloodstream. A preceding viral upper respiratory tract infection may play some role in alterations in local host defense mechanisms that result in bacteremia.^{106,133}

Using human columnar nasopharyngeal tissue in organ cultures, Stephens and colleagues¹⁹⁶ showed that *N. meningitidis* organisms were ingested by the columnar cells, then found within phagocytic vacuoles, and later observed within subepithelial tissues, suggesting that the meningococci had penetrated the epithelial layer. In this same model, Hib organisms attach to nonciliated columnar epithelial cells and subsequently are found in the intercellular spaces in association with a preceding disruption of the tight junctions of epithelial cells.⁶⁰ After passing the mucosal barriers, Hib may enter the bloodstream directly through pharyngeal blood vessels.¹⁷⁹ Pneumococci adhere to specific ligands on respiratory cells. The inflammatory mediators generated

BOX 62.1 Consensus Definitions of Systemic Inflammatory Response Syndrome (SIRS), Infection, Sepsis, Severe Sepsis, and Septic Shock

SIRS

The presence of two or more of the following four criteria, one of which must be abnormal temperature or white blood cell count:

1. Core temperature (rectal, bladder, oral, or central catheter probe) >38.5°C (101.3°F) or <36°C (96.8°F)
2. Tachycardia defined as more than two standard deviations above normal for age in the absence of external factors or drugs *or* otherwise unexplained persistent elevation of a 0.5- to 4-hour time period *or* for children younger than 1 year, bradycardia, defined as a mean heart rate of less than 10th percentile for age in the absence of external factors or drugs *or* otherwise unexplained persistent depression over a 0.5-hour period
3. Mean respiratory rate more than two standard deviations for age *or* mechanical ventilation for an acute process not related to an underlying neuromuscular disease *or* to general anesthesia
4. Peripheral white blood cell count elevated or depressed for age unrelated to medications or more than 10% immature neutrophils

Infection

A suspected or proven (by culture, tissue stain, polymerase chain reaction assay) infection caused by any pathogen *or* a clinical syndrome associated with a high probability of infection

Sepsis

SIRS in the presence of or caused by suspected or proven infection

Severe Sepsis

Sepsis plus one of the following: cardiovascular organ dysfunction, acute respiratory distress syndrome *or* two or more other instances of organ dysfunction as defined in the consensus statement

Septic Shock

Sepsis and cardiovascular organ dysfunction as defined in the consensus statement

Modified from Goldstein B, Giroir B, Randolph A, and the Members of the International Consensus Conference on Pediatric Sepsis. International Pediatric Sepsis Conference: definitions for sepsis and organ dysfunction in pediatrics. *Pediatr Crit Care Med.* 2005;6:2–8.

during viral infections upregulate platelet-activating factor receptor on respiratory cells to which the pneumococci adhere more avidly and subsequently invade.²¹² Pili or adhesins of gram-negative enteric organisms seem to be important in attachment and adherence of these microorganisms to specific receptors expressed on epithelial surfaces. Pili also have been shown to be important in the pathogenesis of some

gram-positive infections, such as *S. pyogenes*, group B streptococcus, and *S. pneumoniae*.^{13,142}

The placement of an endotracheal tube unmasks a greater number of these receptors, presumably through increased protease activity of secretions and decreased cell-bound fibronectin, and leads to colonization of the upper respiratory tract with gram-negative organisms, which are ubiquitous in the environment of an ICU.²⁴³ Biofilm formation on the endotracheal tube surface may contribute to colonization persisting.¹¹⁷ Altered host defense mechanisms allow these organisms to move beyond epithelial surfaces and cause bacteremia.

The gastrointestinal and genitourinary tracts are major sources of gram-negative organisms responsible for bacteremia. These organisms first may cause localized abscesses or peritonitis if intestinal perforation occurs, or they may translocate the intestinal mucosa, particularly when the mucosa is affected by antineoplastic agents. Viridans streptococci can cause bacteremia in a neutropenic patient with severe mucositis that develops after the patient undergoes chemotherapy.¹⁷¹ Microorganisms within the bladder may ascend the genitourinary tract and presumably enter the bloodstream through the kidneys. *S. aureus* and *S. pyogenes* are common inhabitants of the skin and skin structures. Any skin wound or foreign matter within the skin tissue renders the skin more susceptible to bacterial invasion. Staphylococci have a unique capability of adhering to solid surfaces, such as catheters, which may be an important prerequisite to colonization and subsequent catheter-related bacteremia.¹⁶²

The pathophysiology of septic shock is very complex. Septic shock associated with gram-negative organisms has been studied most extensively, especially with respect to endotoxin or bacterial LPS, which has multiple biologic effects. Bacterial LPS has three basic components, as follows:

- 1. Terminal side chains consist of repeating oligosaccharides that differ from strain to strain and are responsible for the antigenic specificity of the O antigens.
- 2. A core LPS also consists of oligosaccharides but has less diversity in structure among strains than do the terminal side chains.
- 3. Lipid A is very similar among the different strains and is responsible for most of the biologic activity of endotoxin.

Endotoxin shock has been the subject of intensive animal research, and much of what is known about the pathogenesis of endotoxin shock has been derived from animal models. Although septic shock in humans is not simulated precisely in these animal models for a number of reasons, including that the animals do not have underlying host defense defects, much of what has been learned about endotoxin shock in animals has been corroborated in the human host.

Endotoxin Shock in Animals

Many animal models of endotoxin shock employ infusions of live gram-negative bacteria, usually *Escherichia coli*, or purified endotoxin, after which observations are made. The effects of purified endotoxin depend partly on the species of animal being studied. Models employing cecal ligation and puncture are thought to be more relevant to human disease than direct infusion of bacteria or endotoxin.²⁴⁶ The effects of endotoxin in animal models are summarized in Table 62.2.

Numerous mediators induced by endotoxin play pivotal roles in the pathogenesis of endotoxin shock. Tumor necrosis factor (TNF), a polypeptide hormone, is a key cytokine mediating septic shock.²⁰⁸ The tissue injury induced by TNF largely is a result of other mediators that are induced by TNF, including interleukin-1 β (IL-1 β), IL-6, eicosanoids, and platelet-activating factor.^{55,96,209,206} TNF is synthesized by a wide variety of cells (including monocytes/macrophages, natural killer cells, microglial cells, hepatic Kupffer cells) after stimulation by LPS, C5a, viruses, and enterotoxins, among other agents. TNF initiates a cascade of events that leads to endothelial cell injury, an enhanced inflammatory response, and, ultimately, the characteristic findings of endotoxic shock.

Nitric oxide (i.e., endothelium-derived relaxing factor) is the final pathway by which endogenous vasodilators stimulated by endotoxin result in hypotension from altered control of microcirculation. LPS through the release of cytokines induces a form of the enzyme nitric oxide synthase II, which leads to increased production of nitric oxide.¹⁴⁰ Inhibitors of nitric oxide synthase, such as N^G-monomethyl-L-arginine, can reverse or prevent hypotension in animals challenged with LPS.¹³²

TABLE 62.2 Endotoxin Shock in Animal Models

Effects	Mediators
Cardiovascular Effects	
Decreased peripheral vascular resistance ¹⁴⁷	Histamine, bradykinin, ¹³⁶ serotonin, complement activation, prostaglandins, anaphylatoxins
Decreased cardiac output ^{6,9,169}	
Depressed myocardial function ¹³⁰	
Decreased systemic blood pressure ⁴³	
Metabolic Effects ¹⁶⁹	
Hyperglycemia ⁴⁸	Hypoinsulinemia
Hypoglycemia ⁶⁴	
Increased adrenocorticotrophic hormone, growth hormone, and antidiuretic hormone ²³⁸	
Decreased calcium ²⁴⁵	
Increased triglycerides ^{107,208}	
Decreased iron, transferrin, and zinc	
Pulmonary Effects	
Congestive atelectasis ^{43,94}	Polymorphonuclear leukocytes
Increased capillary permeability ⁹⁴	Polymorphonuclear leukocytes
Vasoconstriction	Thromboxane, prostacyclin
Bronchoconstriction ²⁹	Leukotrienes
Central Nervous System Effects	
Decreased regional and total cerebral blood flow ¹⁶⁸	
Increased cerebral oxygen consumption ¹⁶⁸	

The pathophysiology of septic shock caused by gram-positive bacteria is similar to that described for gram-negative organisms.¹⁹³ Cell wall components, such as peptidoglycan and teichoic acid, promote proinflammatory activity but are less potent than endotoxin.

Endotoxin Shock in Humans

The pathophysiology of septic shock is highly complex and is related predominantly to actions of endogenous mediators released as part of the systemic inflammatory response to an infection. The cascade of events is intertwining, with production of one cytokine stimulating the synthesis of others; synergistic, in that the activities of certain cytokines act in concert; and sometimes antagonistic, with the production of other molecules to inhibit or compete with various cytokines. This complicated response to an infectious stimulus has been studied best for LPS, but a similar series of events occurs in response to gram-positive infections. Although the best understood system is the one that recognizes bacterial LPS, others exist for sensing the presence of bacterial peptidoglycan, DNA, lipopeptides, flagella, viral double-stranded RNA, and other conserved microbial molecules.

The first host protein involved in the recognition of LPS is LPS-binding protein. LPS-binding protein is an acute-phase protein; its role is to bring LPS to the cell surface by binding to LPS and forming a ternary complex with the LPS receptor molecule, CD14.^{231,244} Formation of the complex between LPS and CD14 facilitates the transfer of LPS to the LPS receptor complex, which is composed of Toll-like receptor 4 (TLR4) and MD2. Studies over the course of several years led to the discovery of the TLR4/MD2 receptor complex as the signaling entity for LPS (Fig. 62.1).¹⁹ MD2 is a secreted glycoprotein that functions as an indispensable extracellular adapter molecule for LPS-initiated signaling events, perhaps by aiding in ligand recognition. The resulting signal promotes mononuclear phagocytes to produce reactive oxygen molecules, cytokines, and arachidonic acid metabolites, including prostaglandin and leukotrienes. A counterregulatory protein is a bactericidal, permeability-increasing protein that is stored in the granules of polymorphonuclear leukocytes and inhibits the effects of LPS.⁷²

FIG. 62.1 Activation of the cytokine network by lipopolysaccharide (LPS). Circulating LPS-binding protein (LBP) recognizes LPS in the plasma and brings it to CD14. This aids the loading of LPS onto the LPS receptor complex, which is composed of dimerized Toll-like receptor 4 (TLR4) receptors and two molecules of the extracellular adaptor MD2. Signals activated by TLR4 can be subdivided into signals dependent on MyD88 (and MAL [MyD88 adaptor-like protein]), which occur early (represented by the events illustrated on the left side of the diagram), and signals independent of MyD88, which occur later and use the adapters TRIF and TRAM (depicted on the right). *Ab*, Antibody; *BPI*, bactericidal/permeability increasing [protein]; *IFNβ*, interferon-β; *IL-1ra*, interleukin-1 receptor antagonist; *IP-10*, interferon-γ-induced protein 10; *IRAK*, interleukin-1 receptor-associated kinase; *IRF3*, interferon regulatory factor 3; *MAPK*, mitogen-activated protein kinase; *MyD88*, myeloid differentiation primary-response gene 88; *NF-κB*, nuclear factor-κB; *RANTES*, regulated on activation, T cell expressed and secreted; *RIP1*, receptor-interacting protein 1; *sTNFR*, soluble tumor necrosis factor receptor; *TAK1*, transforming growth factor-β-activated kinase 1; *TBK1*, TANK-binding kinase 1; *TNF*, tumor necrosis factor; *TRAF6*, TNF receptor-associated factor 6; *TRAM*, TRIF-related adaptor molecule; *TRIF*, Toll/IL-1 receptor domain-containing adaptor inducing interferon-β.

TNF is largely responsible for the biologic effects, including fever, shock, myocardial suppression, capillary leak (i.e., endothelial damage), coagulation alterations, and metabolic changes,^{34,35,134,207,213} of LPS in humans. In children, including neonates, the role of cytokines in sepsis caused by a variety of organisms, but especially *N. meningitidis*, is well documented.^{30,51,78,200,225} LPS and TNF each can induce the synthesis of other proinflammatory cytokines, such as IL-1β and IL-6.⁵⁶ IL-6 levels in plasma correlate with mortality. IL-8 plasma concentrations also are increased after infusion of LPS or IL-1β.^{56,86} Serum IL-8 levels in children with septic shock were predictive of outcome in one study.¹⁹⁴

The antiinflammatory cytokine IL-10 is produced after LPS is injected and inhibits the production of TNF, IL-1β, and IL-6.¹²⁸ Naturally occurring inhibitors of TNF or IL-1β are present in serum samples of patients with the sepsis syndrome.^{79,215,216} IL-1 receptor antagonist (IL-1a) binds competitively to the IL-1 receptor to block the action of IL-1. Soluble TNF receptors bind to circulating TNF, which prevents its proinflammatory actions (see Fig. 62.1).

In adults, gram-negative bacteremia is followed by a decrease in systemic vascular resistance and mean blood pressure and an increase in cardiac output.^{20,233} Decreased systemic vascular resistance may be accompanied by activation of the complement and kinin systems.¹³⁶ After this early phase, the blood pressure decreases further without change in the central venous pressure. Certain patients, especially children, are able to maintain their cardiac output and cardiac index, and this ability may be associated with increased rates of survival. When peripheral

resistance is measured within 12 to 24 hours of the onset of shock, its decrease is significant in patients who survive compared with patients who die.¹⁴⁸ In contrast, cardiac output is reduced significantly in other patients; this decrease is associated with increased concentration of blood lactate, decreased arterial blood pH, and decreased rates of survival.

In one small study, two distinct patterns of septic shock in children admitted to the PICU of a tertiary children's hospital were described.²⁸ Fifteen of 16 children with bacteremia related to central venous lines had a high cardiac index and low systemic vascular resistance. This pattern was seen in only 2 of 14 children with community-onset infections in whom normal or low cardiac index with variable systemic vascular resistance was typically noted.

Depression of myocardial function has been shown in adult and pediatric patients in septic shock.⁶³ These patients have a reduced ejection fraction, left ventricular dilation, and significantly altered ventricular performance in response to infusion of volume.¹⁵⁰ This depression of myocardial function is transient in survivors, however, reverting to normal within 1 to 4 days.¹⁵³ Parker and colleagues¹⁵⁴ found that patients who did not survive septic shock did not have left ventricular dilation or reduction in the ejection fraction. When the systemic vascular resistance index was averaged over the course of time, nonsurvivors had a significantly lower ($P < .05$) index than that of survivors of septic shock. This study included three children who were 9 to 17 years of age. Abraham and associates¹ sequentially monitored hemodynamic

and oxygen transport measurements in 33 patients with septic shock. In the 24-hour period before the onset of hypotension, the survivors showed significantly greater cardiac index, left cardiac work index, oxygen delivery, and oxygen consumption than the nonsurvivors.

A circulating myocardial depressant factor in patients with septic shock was proposed more than 50 years ago, but myocardial dysfunction was not quantitatively linked to a serum factor until the late 1980s.^{130,155,170} Kumar and colleagues¹¹³ later reported that the myocardial depressant activity of sera obtained from patients with septic shock could be eliminated by the immunoprecipitation of TNF and IL-1 β . Several investigators also have shown that TNF and IL-1 β synergistically depress myocardial function in vitro and that this effect can be abolished by an inhibitor of nitric oxide.^{33,152} Germane to this discussion is the observation that LPS-induced biosynthesis of TNF mRNA and protein is not strictly confined to peripheral mononuclear cells but also may occur within many different tissue compartments. Experimental studies have shown that the cardiac compartment can be a significant source of TNF during septic shock. Kapadia and colleagues¹⁰² showed that administration of LPS leads to intramyocardial production of TNF mRNA and protein in vivo. These observations raise the possibility that the myocardial depression occurring in sepsis may develop directly in response to the compartmentalized production of TNF and other cytokines within the heart, as opposed to systemic production of these mediators by circulating mononuclear cells. TLR4 is expressed in the heart, and investigators have suggested that it is involved in signaling the cytokine production induced by LPS within the heart.¹⁶ The complex interactions leading to myocardial dysfunction or "septic cardiomyopathy" are incompletely understood but remain an area of active investigation.⁷⁰

In children, the most comprehensive investigation of myocardial dysfunction has been in meningococcal septic shock. Thiru and coworkers²⁰² measured serum concentrations of the cardiac muscle-specific protein cardiac troponin I, which is released from injured cardiac myocytes, in 101 children with meningococcal septicemia. Minimum left ventricular ejection fraction was inversely related to peak cardiac troponin I levels. The degree of myocardial dysfunction, as determined by inotrope measurement, was related directly to peak cardiac troponin I concentrations. Their results suggested that myocardial cell death might contribute, at least in part, to the cardiac dysfunction associated with meningococcal septic shock.

Hematologic changes, such as leukocytosis, leukopenia, and thrombocytopenia, have been observed in human volunteers after receiving an infusion of endotoxin. Thrombocytopenia commonly occurs in association with sepsis of any cause.⁴⁵ Septic shock is one of the most common causes of disseminated intravascular coagulation in children. Hageman factor (i.e., factor XII), which initiates the coagulation cascade, can be activated directly by LPS or through endothelial damage induced by bacteria.¹²⁴ In septic shock, concentrations of Hageman factor, prekallikrein, high-molecular-weight kininogen, and factor VII are decreased partly as a result of consumption.^{47,101} Similarly, levels of inactivators of clotting factors, such as C1 esterase inhibitor, α_2 -macroglobulin, and antithrombin III, also are diminished. Corrigan and Jordan⁴⁷ diagnosed disseminated intravascular coagulation in 24 of 26 children with septic shock and found that improvement in coagulation parameters seemed to be related most to restoration of blood pressure. A disseminated intravascular coagulation score using four components (platelet count, fibrinogen concentration, fibrin degradation products, and prothrombin time) was found to correlate with mortality in children with sepsis or septic shock.¹⁰⁸ Gram-negative bacteremia may be associated with a coagulopathy that is not disseminated intravascular coagulation but is characterized by prolongation of the prothrombin and partial thromboplastin times caused by a reduction in the vitamin K-dependent coagulation factors.⁴⁶

LPS or cell wall components of gram-positive organisms, through cytokine production, activate blood coagulation predominantly through the extrinsic pathway. The procoagulant state is enhanced further by decreased protein C activity, which is an important inhibitor of coagulation factors Va and VIIIa. The fibrinolytic system also is altered by endotoxemia and is mediated by plasminogen activator inhibitor 1-induced suppression. The coagulopathy associated with septic shock is

characterized by a procoagulant state and inhibition of fibrinolysis.^{118,121} Protein C has antiinflammatory properties. The antithrombotic, profibrinolytic, and antiinflammatory actions of activated protein C counteract the effects of cytokine activation, but a deficiency of protein C may be acquired during severe sepsis. Low levels of protein C have been associated with increased morbidity and mortality rates in patients with severe sepsis and septic shock.⁶⁷ For meningococcal disease in particular, dysfunction of the protein C activation pathway is a key factor in the development of the thrombosis associated with purpura fulminans. Downregulation of the endothelial thrombomodulin-endothelial protein C receptor pathway seems to be the mechanism for impaired activation of protein C during severe meningococcal sepsis.⁶¹ Cytokine increases also lead to elevated serum ferritin levels during severe sepsis and septic shock; in one pediatric study levels higher than 500 ng/mL were associated with greater mortality.⁷⁴

LPS can activate the complement cascade by the classic or the alternate pathway. Significantly depressed concentrations of C3 occur in patients with bacteremia and hypotension compared with normal individuals or with patients with uncomplicated bacteremia, and C3 is activated primarily by the alternate pathway.^{62,101,126} In patients with bacteremia and hypotension, C1, C4, and C2 levels were not depressed significantly from values found in normal controls or in normotensive patients with bacteremia. In contrast, C3, C5, C6, C9, properdin, and factor B levels were decreased significantly ($P < .05$) in bacteremic patients with shock. In children with meningococcal disease, Tubbs²¹¹ found a mean C3 concentration (as a percentage of normal values) of $132\% \pm 21\%$ for survivors versus $91\% \pm 21\%$ for nonsurvivors. The C3 levels did not correlate with endotoxin levels in sera.

Many metabolic alterations have been documented in the human host during endotoxin shock. Hyperglycemia followed by hypoglycemia can complicate the shock state induced by sepsis.^{64,137} Whole-body use of glucose is increased during sepsis, which probably is cytokine mediated.¹³⁸ Glycolysis and gluconeogenesis are increased, but insulin resistance occurs in skeletal muscle. Children with underlying liver disease or with reduced glycogen stores are most likely to develop hypoglycemia during septic shock. Lactic acidosis develops as a result of poor tissue perfusion and cellular hypoxia. Lactic acid concentrations are increased in nonsurvivors and patients with poor or low-flow cardiac output during sepsis.

In clinical studies, Clowes and associates⁴¹ identified a subgroup of patients with low-flow septic shock in whom concentrations of serum insulin were lower than concentrations in a control population. In children with meningococcal sepsis, van Waardenburg and colleagues²²¹ found higher blood glucose concentrations and significantly lower insulin levels on day 2 or 3 of hospitalization in children with shock compared with children without shock. Levels of plasma insulin and soluble TNF receptor 75 were inversely correlated in these children. Their findings were consistent with the inflammatory response inhibiting insulin secretion. In another study of meningococcal sepsis, both insulin resistance and β -cell dysfunction contributed to the hyperglycemia that occurred in a third of the children.²²²

Hypocalcemia and decreased serum ionized calcium concentrations occur frequently during bacterial sepsis. In one study, 12 (20%) of 60 critically ill adults with bacterial sepsis had hypocalcemia.²⁴⁵ The mortality rate in the hypocalcemic patients was 50% compared with 30% in the patients who were normocalcemic. Cardenas-Rivero and associates³⁷ studied calcium homeostasis in 145 children admitted to an ICU. Of eight children with confirmed sepsis or meningitis (or both) not caused by Hib, seven had hypocalcemia, and six of seven had ionized hypocalcemia. Five of the six children with ionized hypocalcemia had inappropriately normal concentrations of parathyroid hormone, which suggests that transient hypoparathyroidism occurs in some children with sepsis. Hypocalcemia also occurs commonly in patients with toxic shock syndrome.²³⁷ In women with toxic shock syndrome and hypocalcemia, serum concentrations of calcitonin are elevated by unknown mechanisms.³⁹ Hypocalcemia and elevated calcitonin concentrations also have been documented in children with fulminant meningococemia.¹²²

Procalcitonin levels are elevated in several conditions associated with SIRS, including sepsis, and have been proposed as adjunctive

laboratory tests for the early detection of, and indicators for prognosis of, meningococcal disease and many other infections.^{38,88,114} These changes in calcium levels are especially critical because the level of ionized calcium and cardiac output in septic shock can be correlated.²⁴² Other metabolic changes may occur during septic shock in humans, as follows:

1. Increased concentrations of cortisol and growth hormone (including in neonates)^{204,226}
2. Relative adrenal insufficiency by adrenocorticotropin testing⁹⁰
3. Depression of triiodothyronine and thyroxine levels related to poor nutrition¹⁷⁵
4. Elevations in total concentrations of amino acid in plasma and the preferential use of branched-chain amino acids as an energy source for skeletal muscle¹³⁸
5. Muscle proteolysis, possibly induced by one or more circulating agents in the plasma of patients with serious infections⁴⁰
6. Elevations in concentrations of plasma thromboxane, which are observed in nonsurvivors of septic shock¹⁷³
7. Elevations in concentrations of triglycerides and free fatty acid during gram-negative bacteremia^{73,107}
8. Altered zinc homeostasis²⁴⁰

Liver dysfunction is an important aspect of endotoxin shock in adults. Banks and colleagues¹¹ found that clinical jaundice was apparent in 63% of their patients with septic shock, that it was found more commonly in nonsurvivors than in survivors, and that the degree of biochemical liver abnormalities was related to the duration of shock. Postmortem findings included focal liver necrosis, Kupffer cell hyperplasia, portal tract inflammation, venous congestion, and intra-hepatic cholestasis.

Adult respiratory distress syndrome (ARDS), or shock lung, is a major complication of septic shock in children.^{97,164} The lungs of children with ARDS have characteristic changes consisting of increased lung weight reflecting congestion and atelectasis, alveoli lined with hyaline membranes, microthrombi, hemorrhage, and interstitial edema.⁹⁷ Increased capillary permeability and intrapulmonary shunts have been documented in patients with ARDS.⁴⁹ C5a, a potent chemotactic factor, causes aggregation of polymorphonuclear neutrophils, is elevated in the sera of patients who ultimately develop ARDS, and is found in increased concentrations in bronchoalveolar lavage fluid obtained from patients with ARDS.^{87,176} Leukocyte aggregates are thought to be trapped in lung tissue and may cause damage to the endothelium of the pulmonary microvasculature through the release of oxygen radicals, lysosomal enzymes, and products of arachidonic acid metabolism. Although neutrophils play a critical role in the pathogenesis of ARDS, other factors also are important, considering that ARDS can develop in patients who are neutropenic.^{149,234} Thromboxane, platelet-activating factor, fibrin, and other substances contribute to the lung injury in ARDS.¹⁷⁸

The effects of endotoxin shock on the central nervous system have not been studied carefully in humans.⁸⁴ The encephalopathy associated with sepsis seems to be caused partly by altered phenylalanine metabolism; concentrations of phenylalanine and its metabolite, phenylacetic acid, are increased in the sera and cerebrospinal fluid of septic adults who are stuporous or comatose.¹³⁹

Endotoxin has been implicated in the pathogenesis of acute renal failure associated with sepsis. Wardle^{227,228} showed that 12 of 16 patients with acute tubular necrosis had endotoxemia. Renal arterial blood flow and renal vascular resistance are decreased significantly in baboons 2 to 4 hours after infusion of endotoxin. Inadequate perfusion pressure was associated with renal ischemia and negligible urine output in these animals shortly after administration of endotoxin.¹⁸⁴ Pathologic examination of the kidneys revealed focal necrosis of the proximal tubular epithelium, eosinophilic casts within proximal and distal tubules, and microthrombi in the glomerular capillaries. Endothelin, a potent vasoconstrictor peptide produced by endothelial cells, is elevated in concentration in the plasma of patients with septic shock. Because endothelin contributes to the regulation of regional blood flow, elevated levels suggest that it may relate to renal vasoconstriction and dysfunction.²²³

Endotoxin can be measured in the plasma of patients with gram-negative bacteremia as well as in patients with other infections, even

upper respiratory tract infections.⁵³ The presence of circulating endotoxin does not mean that bacteremia is present or ever has occurred because endotoxin presumably may be “absorbed or leak” into the circulation from the gastrointestinal tract.^{119,199,210} Endotoxemia may be a valid indicator, however, of impending gram-negative septicemia in febrile patients.²¹⁷ Preformed antibody to LPS or lipid A is associated with protection against shock and death caused by gram-negative bacteremia in adults. McCartney and colleagues¹²⁸ detected endotoxin in the blood (after chloroform extraction) of patients with gram-negative septic shock; all 18 patients with persistently positive endotoxin assays died. In contrast, nine patients who initially had endotoxemia but subsequently had negative assays survived. Other studies confirm the association between endotoxemia and outcome.^{218,123} Evidence exists that human endotoxin is cleared from the circulation by the liver and can be detoxified by neutrophil enzymes (i.e., acylxacyl hydrolases).^{125,143}

The sequence of events in the evolution of endotoxin shock has been outlined by several investigators.¹⁴⁷ Bacteria, endotoxin, or other bacterial products stimulate the production of TNF and other cytokines, which in concert with endotoxin set off a whole series of events. Potent mediators, including C3a, C5a, eicosanoids, platelet-activating factor, histamine, and myocardial depressant substance, are released. Potent vasodilators cause peripheral vasodilation, and decreased systemic peripheral resistance leads to pooling of blood and decreased venous return to the heart. Mean blood pressure may be low, or it may be normal if cardiac output increases sufficiently to compensate for these alterations despite depression of ventricular function. The central venous pressure, which partially depends on myocardial performance, may be low or in the normal range.

If intravascular volume is increased by the administration of sufficient fluids, shock may be prevented or corrected. Continued hypotension and diminished perfusion pressure may lead, however, to cellular hypoxia and increased production of lactic acid from pyruvate. The microcirculation is altered by local tissue acidosis. Capillary beds become congested, and intravascular fluid may leak into the interstitial spaces. Increased secretion of catecholamine leads to arteriolar and venular constriction and increased peripheral resistance. Pooling of blood is enhanced, which leads to a further diminution in venous return and a reduction of cardiac output. Oliguria, coagulation abnormalities, and additional metabolic alterations indicate multiple organ system failure and presage the death of the patient.

Wong et al.²³⁹ have studied the genome-level expression profiles of children with sepsis and septic shock. Multiple gene networks, primarily related to inflammation and immunity, were affected over time and were differentially regulated.¹⁸⁷ These investigations have led to the identification of three subclasses of distinct gene expression profiles; higher mortality is associated with one of these subclasses.²⁴¹ This type of classification scheme might be able to identify patients at the time of admission who are at greater risk for poor outcomes and who would be optimal candidates for studying newer interventions or strategies for treating children in septic shock.

Genetic polymorphisms in the immune response to infection have been shown to be associated with clinical outcomes.²⁰¹ Functional and association studies involving genetic polymorphisms in essential genes, including Toll-like receptors, cytokines, and coagulation factors, have provided important insights into the mechanisms involved in the pathogenesis of sepsis-induced organ dysfunction. Precise categorization of patients based on genetic background may lead to individualized targeted treatment.

CLINICAL PRESENTATION AND DIAGNOSIS

The signs and symptoms of bacteremia vary greatly depending on the age and underlying disease of the patient, the duration of illness, and the specific microorganisms. Young, otherwise healthy children aged 3 months to 3 years may present with fever and evidence of an upper or lower respiratory tract infection or no focus of infection and yet have unsuspected bacteremia. Most studies indicated that the risk of developing bacteremia increases as the body temperature increases, and, in the unimmunized child, almost 25% of these children may be bacteremic after the temperature exceeds 41°C.¹⁴ In a previously healthy child, the

persistence of irritability and the inability to console the child despite optimal environmental conditions have been proposed as key points in the physical examination that should alert the clinician to the possibility of a serious infection such as bacteremia or meningitis.^{127,191}

Underlying illnesses with splenic dysfunction place a child at increased risk for serious infections caused by encapsulated organisms, whereas children with leukemia or other immunosuppressive diseases or children in the ICU are more likely to be infected with gram-negative bacilli or *S. aureus*. A history of diarrhea may suggest *Salmonella* spp. as a possible cause of illness. Preceding skin infections or wounds are important clues to infection caused by *S. aureus* or group A streptococcus. An indwelling vascular catheter may precipitate overlying erythema in a patient with evidence of phlebitis proximally. Gram-positive cocci, gram-negative bacilli, and yeast can be associated with catheter-related sepsis. Toxic shock syndrome should be considered in a hypotensive girl or woman with a recent menstrual period and history of tampon use, although toxic shock also is associated with *S. aureus* sepsis in males and nonmenstruating females.^{82,189} Evidence of osteomyelitis, with or without venous thrombosis, is a very common finding in staphylococcal sepsis. Intraabdominal sources of infection increase the likelihood of developing anaerobic bacteremia.

Petechiae may be associated with many microorganisms, especially invasive disease caused by *N. meningitidis*.²¹⁹ Purpura is an ominous finding and frequently is associated with overwhelming infection caused by *N. meningitidis*, *S. pneumoniae*, and Hib. *P. aeruginosa* is associated specifically with erythema gangrenosum.⁵⁷ Almost half of children presenting with erythroderma (diffuse erythema) either had shock at presentation or developed shock in one study.³² Other skin and soft tissue manifestations of gram-negative sepsis include bullous lesions, cellulitis, fasciitis, thrombophlebitis, and symmetrical peripheral gangrene with disseminated intravascular coagulation.¹⁴⁴ Signs of meningeal irritation or increased intracranial pressure are important because they may modify the approach to management of fluids in a child in shock.

The onset of bacteremia may be heralded by chills, fever, nausea, vomiting, diarrhea, rashes, and petechiae. Initially, the skin feels warm and appears flushed. A change or impairment in mental status may be the first clue to the presence of shock. Hyperventilation also may develop before the onset of clinical shock occurs, which can alert the physician to impending circulatory insufficiency.²¹ In time, cold, clammy extremities; a weak pulse; tachycardia; tachypnea; hypotension; and oliguria may occur. The skin over the extremities, the tip of the nose, and the earlobes especially are prone to cyanosis. Auscultation of the lungs may reveal rales, indicating pneumonia or pulmonary edema. Abnormal distention or tenderness to palpation and guarding may be evidence of peritonitis. Costovertebral angle tenderness suggests acute pyelonephritis as a source of bacteremias.

The physician must distinguish among the following three main types of shock in children:

1. *Hypovolemic shock*, such as occurs with blood loss, fluid and electrolyte loss, adrenal insufficiency, or other causes
2. *Cardiogenic shock*, which is associated with drug intoxication, cardiac surgery, arrhythmias, and pericardial tamponade, among other causes
3. *Distributive shock*, which indicates abnormal distribution of blood flow leading to inadequate tissue perfusion (e.g., septic shock, anaphylaxis)

The laboratory evaluation of a child with bacteremia, septic shock, or both conditions should provide information concerning the cause and the data required for optimal supportive management. Several studies showed that a total white blood cell (WBC) count exceeding 15,000 cells/mm³ in a 3- to 36-month-old child who has not been immunized with conjugate vaccines and with a temperature greater than 39°C to 40°C and without a focus of infection is an indication that the child is at increased risk for having bacteremia, especially pneumococcal bacteremia.¹² Since the introduction of the pneumococcal conjugate vaccine, pneumococcal bacteremia in this scenario has been greatly reduced.^{92,183,198} Elevated erythrocyte sedimentation rates and C-reactive protein levels also have been suggested as useful screening tools for detecting serious bacterial infections. A low peripheral WBC

count also may suggest septicemia and commonly is observed during episodes of overwhelming bacteremic illnesses.

Procalcitonin levels are elevated in bacteremic children and are related to the severity of illness, such as organ failure and even death.^{88,114} Commercial kits for the rapid measurement of concentrations of procalcitonin are available. Hemoglobin and hematocrit results should help differentiate between septic and hemorrhagic shock. Examination of the peripheral smear may disclose evidence of splenic dysfunction (i.e., Howell-Jolly bodies) or fragmented red blood cells, as seen in disseminated intravascular coagulation. Thrombocytopenia, prolongation of prothrombin time and partial prothrombin time, and the presence of fibrin split products are consistent with disseminated intravascular coagulation.

Hyponatremia is a common finding. Concentrations of serum bicarbonate may be depressed, which may signify a state of metabolic acidosis. Elevated lactic acid concentrations result from inadequate tissue perfusion and, in some reports, have been significantly greater in nonsurvivors or patients with low-flow states than in survivors or patients with high-flow shock.⁴¹ In pediatric studies, serial lactate levels showing normalization are associated with recovery.⁵⁸ Hyperglycemia or hypoglycemia may be encountered. In one study, serum glucose levels greater than 178 mg/dL were associated with a greater risk of death caused by septic shock.²⁶ Transaminase levels may be elevated and presumably reflect cellular injury. Serum calcium concentrations (preferably ionized calcium levels) should be checked periodically because hypocalcemia may interfere with optimal myocardial function.

A chest radiograph may reveal a pulmonary source of infection or show a secondary pulmonary manifestation of an invasive infection such as pneumonia or septic emboli in children with staphylococcal sepsis.⁵¹ Arterial blood gases obtained early in endotoxin shock usually reveal hypocapnia and normal to elevated pH.^{21,22} At this point, the patient has a mixed metabolic acidosis and respiratory alkalosis. If the shock state progresses, the metabolic acidosis becomes so severe that respiratory compensation is ineffective, and the patient becomes acidotic. In some patients, respiratory acidosis accompanies metabolic acidosis. In either case, decompensated metabolic acidosis in a patient with septic shock is associated with a grave prognosis. A major consequence of ARDS is hypoxemia. For patients with ARDS, the chest radiograph characteristically shows bilateral and diffuse hazy infiltrates; opacification of all lung fields usually is seen during the late phases of ARDS. Positive fluid balance contributes to the pulmonary dysfunction in patients with acute lung injury, including those related to sepsis.⁶⁹

Concentrations of blood urea nitrogen and serum creatinine may be elevated. Jones and Weil¹⁰⁰ found that the ratio of urine to plasma osmolality was the most valuable indicator of renal impairment in adult patients with shock. When this ratio was greater than 1.5, the likelihood of developing progressive renal failure was remote. A urine osmolality value greater than 400 mOsm/kg also indicated adequate renal function. Gene microarray studies may identify novel biomarkers that identify a patient in septic shock who is at greater risk for acute kidney injury.¹⁵ Many WBCs or WBC casts in the urine may suggest the genitourinary tract as the source of bacteremia. If one or more gram-negative rods are seen on the Gram stain of unspun urine, more than 10⁵ colony-forming units/mL of bacteria are likely to be present.

Isolating the organism responsible for bacteremia or septic shock is important for documenting the infection and for providing optimal antimicrobial therapy. With instruments that continuously monitor growth in the blood culture bottles, growth can be detected sooner than if the bottles are inspected just once or twice daily. Before the use of the pneumococcal conjugate vaccine became routine, many authorities recommended that a blood culture be obtained in a 3- to 36-month-old child with temperature greater than 39°C to 40°C and a total WBC count greater than or equal to 15,000 cells/mm³ and without a specific focus of infection. In this way, instances of "unsuspected" or "outpatient" bacteremia could be identified. In an outpatient setting, almost 90% of blood cultures growing true pathogens were positive within 24 hours of incubation using a continuously monitored system.¹³¹ This approach is now less useful in the era of administration of pneumococcal conjugate vaccine to young infants.⁹⁹

In an infant who has received three or more doses of the conjugate pneumococcal vaccine, the likelihood of developing invasive pneumococcal

infection is reduced approximately 90%. The proportion of children with high fever without localizing findings and a WBC count of 15,000/mm² or greater who might have occult pneumococcal bacteremia may be less than 1%, a level that no longer justifies this approach. Most organisms isolated from blood cultures in these patients are now more likely to be a contaminant than a true pathogen. Currently, the approach to a febrile child without a source has changed in many emergency departments such that more selective criteria for obtaining blood cultures are being developed.

When appropriate, cerebrospinal fluid, urine, and other pertinent sites should be cultured before initiating antibiotic therapy, if possible. When an intraabdominal source of infection is likely, blood and other cultures should be processed anaerobically. Gram stain or acridine orange stain of a buffy coat smear of peripheral blood may reveal evidence of the causative microorganism, especially in an overwhelming infection.¹¹⁰ Gram stain of material obtained from petechial or purpuric lesions may show gram-negative diplococci suggestive of meningococcus. Polymerase chain reaction for detecting *N. meningitidis* is available in selected laboratories and may be the only method by which infection is documented when cultures are sterile. The development of newer molecular techniques hopefully will lead to a greater availability of tests to detect a wider range of pathogens rapidly.

TREATMENT

The initial selection of antibiotics for administration to a child with suspected bacteremia is based on the clinical situation (Table 62.3). If untreated initially, children with occult bacteremia are at risk of developing serious complications, such as meningitis or pneumonia.^{123,145} Empiric antibiotic therapy for children who are selected carefully and followed seems reasonable.^{12,14,68}

In children who have not received more than two doses of the pneumococcal conjugate vaccine, one approach may be to obtain a blood culture from children aged 3 to 36 months with a temperature of 39°C or greater who have no focal findings and whose peripheral WBC count is greater than or equal to 15,000/mm². In such patients, the decision to administer antibiotics expectantly may be based on several factors, especially the ability of the parents to observe the child and communicate this information back to the physician in a timely manner. Ceftriaxone given parenterally, an oral agent such as amoxicillin and amoxicillin-clavulanate, or other oral antibiotics can be administered. If treatment is initiated, a properly collected urine specimen for urinalysis or urine culture also should be obtained so that a urinary tract infection would not be treated inadvertently since UTI is now the most common serious bacterial infection in young children with fever without a source.⁹⁹

TABLE 62.3 Empiric Antibiotic Regimens for Septic Shock in Infants and Children Under Selected Clinical Circumstances

Circumstances	Antibiotics
Normal Child	
Skin findings suggesting meningococcemia or preceding skin trauma or varicella	Cefotaxime or ceftriaxone + vancomycin ± nafcillin
Urinary tract source	Cefotaxime or ceftriaxone + aminoglycoside
Intraabdominal source	Clindamycin or metronidazole + gentamicin + piperacillin-tazobactam
Immunocompromised Child	
Malignancy or immunodeficiency or neutropenia or central line	Vancomycin + aminoglycoside + piperacillin-tazobactam or ceftazidime
Asplenia or splenic dysfunction	Vancomycin + cefotaxime or ceftriaxone

Occult bacteremia caused by *S. pneumoniae* intermediate or resistant to penicillin or intermediate to ceftriaxone in an otherwise normal child should resolve with any of the options noted earlier.¹⁰⁴ This approach probably is less useful in an infant or child who has received three or more doses of the conjugate pneumococcal vaccine.

Children who subsequently are determined to have *S. pneumoniae* bacteremia and who have been treated with antibiotics expectantly need to be reevaluated as soon as the results of the blood cultures are known. If the child appears well and has been afebrile for at least 24 hours and if the parents can observe the child carefully and are able to communicate frequently with the physician, outpatient management can be continued. For children who were not treated initially, who remain febrile, and who are called back to be reevaluated for a positive blood culture, a parenteral dose of antibiotics is recommended.¹⁰ It is in this situation where rapid identification of gram-positive cocci growing in blood cultures is particularly helpful. Determining that the organism growing is coagulase-negative staphylococcus by molecular tests (GenXpert) may avoid calling the patient back because of a blood culture contaminant. Close contact with the parents and patient is mandatory no matter how these children are managed initially. Hospitalization for intravenous antibiotics is indicated if the child appears “toxic” or has other signs suggesting a serious infection.

For children with suspected bacteremia who are ill and require admission to the hospital, antibiotics are selected to cover the most serious organisms causing that infection. In normal children aged 3 months or older, a combination of nafcillin (150 to 200 mg/kg per day) or another semisynthetic antistaphylococcal penicillin plus cefotaxime (150 to 200 mg/kg per day) or ceftriaxone (75 to 100 mg/kg per day) covers most of the likely pathogens (e.g., *S. pneumoniae*, *S. aureus*, *S. pyogenes*, *N. meningitidis*, Hib). In areas of the world where community-acquired MRSA is a problem, an agent effective against MRSA should be included in the initial empiric regimen.^{91,103} Vancomycin (45 to 60 mg/kg per day) is the gold standard for treating infections caused by MRSA. Adding an aminoglycoside or rifampin to vancomycin is not beneficial.¹²⁰ Although most community-acquired MRSA isolates are susceptible to clindamycin, this agent is not generally recommended alone for bacteremic illness since it is not bactericidal. Some experts recommend adding clindamycin to vancomycin or nafcillin theoretically to reduce toxin production. This reduction occurs in vitro, but no clinical data indicate that this approach leads to a decrease in the incidence of morbidity or mortality.¹⁹⁷

Treatment of bacteremia associated with a genitourinary or gastrointestinal source requires antibiotics to which gram-negative enterics are susceptible. In such cases, initial therapy could consist of an aminoglycoside with an additional antibiotic active against anaerobes, such as clindamycin, metronidazole, or piperacillin-tazobactam, for a gastrointestinal focus of infection. Extended-spectrum cephalosporins, such as cefotaxime, ceftriaxone, or cefepime are the most commonly recommended drugs for treating serious gram-negative enteric infections. Optimal management of intraabdominal or other abscesses usually requires surgical drainage, which should be undertaken as soon as the child's condition allows.

Immunosuppressed children or children with serious illnesses in the ICU require a different initial approach to suspected bacteremia. Gram-negative enterics, *P. aeruginosa*, *S. aureus*, and coagulase-negative staphylococcus are likely to be isolated from these patients. Empiric therapy of nosocomial infection is based on the current antibiotic susceptibility pattern within the hospital.²⁰⁵ *E. coli*, *Klebsiella* spp., and *Enterobacter* spp. are among the most common organisms causing bacteremia in patients in the pediatric ICU.¹⁷⁴ *E. coli* and *Klebsiella* spp. frequently produce β-lactamases that lead to resistance to piperacillin. Generally a combination of an antistaphylococcal semisynthetic penicillin or vancomycin (if a central line is present) or, if MRSA is a relatively common nosocomial pathogen, an aminoglycoside and an extended-spectrum penicillin (e.g., piperacillin-tazobactam), or a third- or fourth-generation cephalosporin (cefotaxime, ceftazidime, cefepime) is administered initially until a specific pathogen is isolated. Broad-spectrum penicillins and aminoglycosides frequently exhibit synergy in vitro against gram-negative organisms, especially against *P. aeruginosa*.¹⁸⁸ In critically ill patients, it is not clear that a synergistic

combination of antibiotics is beneficial for treating bacteremia caused by *P. aeruginosa* or gram-negative enteric rods.^{93,111,160} Combination therapy may be helpful in the neutropenic patient with bacteremia, especially due to *P. aeruginosa*. When administering two different classes of antibiotics directed against gram-negative organisms, it is most beneficial to have at least one antibiotic active in vitro against the causative pathogen prior to knowing the antibiotic susceptibilities.

After a specific organism is identified and antibiotic susceptibilities are known, the most appropriate agent is selected. If *E. coli* or *Klebsiella* spp. are isolated, these organisms can produce extended-spectrum β -lactamases (ESBL). With the current Clinical and Laboratory Standards Institute breakpoints, the ESBL-producing bacteria should be detected.^{42,157} If an ESBL-producing organism is identified, treatment with an extended-spectrum cephalosporin (e.g., cefotaxime, ceftriaxone, ceftazidime) is not recommended.¹⁵⁹ In this case, a carbapenem, such as imipenem-cilastatin or meropenem, is suggested.¹⁵⁹

Enterobacter spp., *Citrobacter* spp., and *Serratia marcescens* may hyperproduce β -lactamase enzymes or be induced to hyperproduce these enzymes and are resistant or can become resistant to the extended-spectrum cephalosporins.¹⁶³ In many institutions, a high percentage of these isolates are resistant to ceftazidime.³¹ Cefepime may be more active than is ceftazidime or cefotaxime against *Enterobacter* spp. and other Amp C, β -lactamase enzyme-producing, gram-negative bacilli.¹⁸² A carbapenem with an aminoglycoside is the treatment regimen recommended for treating infections caused by these isolates when resistant to the third-generation cephalosporins.

In these patients, rapidly achieving therapeutic aminoglycoside levels in the plasma is important.¹⁴¹ Serum concentrations of the aminoglycoside should be measured within 24 hours of initiation of therapy to ensure that therapeutic concentrations have been reached. Higher doses of antibiotics than normally administered may be required in some patients.

Antibiotics should be administered as soon as the diagnosis of septic shock is suspected. The Surviving Sepsis Campaign (SSC) endorses administering antibiotics within 1 hour of shock recognition.⁵² In adults, a delay in treatment with appropriate antibiotics is associated with increased mortality.¹¹² Weiss and associates²³⁵ reported on the impact of antimicrobial timing on mortality and organ dysfunction in pediatric patients with severe sepsis or septic shock at a single institution. These investigators noted that delayed administration of initial and first appropriate antibiotic therapy beyond 3 hours from recognition of severe sepsis and septic shock were independent risk factors for mortality. This study, however, was not powered to address the SSC recommendation of administering empiric antibiotics within 1 hour of sepsis recognition. Ames and associates⁷ have also evaluated the effect of empiric and appropriate antibiotic administration in the emergency department on the development of new or progressive MODS. In this study, 48% (153/321) of pediatric patients admitted to the intensive care unit received empiric antibiotics in 1 hour or less. Early (≤ 1 hour), appropriate antibiotics were administered to 36% (56 of 154) of patients with a documented bacterial infection. Although these patients had significantly greater PIM2 scores, rates of new or progressive MODS (15% vs. 15%) and hospital mortality (10% vs. 6%) were similar to those of patients treated at more than 1 hour. These two studies suggest that a multicenter study will be needed to determine the ideal time goal for early appropriate antibiotic treatment that will improve patient outcomes.

The selection of antibiotics is the same as that for bacteremia. If *S. aureus* is suspected among the potential causes of septic shock, antibiotic therapy is complicated by two factors: MRSA may make up more than 50% of community-acquired isolates,¹⁰³ and nafcillin or oxacillin is superior to vancomycin for the treatment of serious infections caused by methicillin-susceptible *S. aureus*.⁸³ Nafcillin or oxacillin plus an aminoglycoside may be synergistic against staphylococci, but adding an aminoglycoside increases the risk for nephrotoxicity to develop. Some authorities include nafcillin or oxacillin plus vancomycin plus gentamicin in the initial empiric therapy of patients with life-threatening infections possibly caused by *S. aureus*.¹⁶¹ Combination empiric antibiotics appear to be advantageous because it is more likely that an antibiotic active against the causative pathogen will be administered compared with empiric monotherapy and not because of potential synergy.⁵⁴

The management of septic shock is directed toward three main objectives: (1) control of the infectious process, (2) restoration of adequate tissue perfusion, and (3) maintenance of efficient respiratory function. Providing aggressive fluid resuscitation early in the emergency center proved to be one factor in decreasing the length of hospital stay in one study.¹¹⁵ Details of management have been the subject of numerous reports.^{36,109,180} The reader is referred to these reviews for expert detailed guidance in the fluid management, use of vasoactive agents, and respiratory treatments in children with septic shock.

The benefits of therapy with high doses of corticosteroids in the treatment of endotoxin shock remain unproved. Extensive experimental data document the salutary hemodynamic, metabolic, microcirculatory, and cellular effect of steroids in laboratory models of endotoxin shock.⁹⁵ High-dose steroids were never found to be efficacious, however, in randomized controlled trials conducted in adults with severe sepsis or septic shock.^{25,192} In a recent meta-analysis, 35 randomized trials (4682 adult patients) were reviewed.²²⁴ Fourteen trials evaluated high-dose steroids and 21 used low-dose steroids. The authors concluded that there was no evidence for a beneficial effect of steroids in patients with SIRS, sepsis, severe sepsis, or septic shock.

On the basis of these studies, the routine use of high-dose corticosteroids in patients with severe sepsis or septic shock is not recommended. Results of randomized studies enrolling adults suggested that lower stress doses of hydrocortisone might be beneficial in managing patients with septic shock.^{23,27} However it is not clear if there is a survival benefit at 28 days.¹⁵⁶ The role of low-dose hydrocortisone in children with septic shock remains controversial.^{8,220} In one pediatric study the addition of fludrocortisone, a mineralocorticoid given enterally, to parenteral hydrocortisone was associated with shorter duration of norepinephrine support but more hypokalemia in children with sepsis.⁸⁹ Randomized studies are needed to clarify the role of stress doses of hydrocortisone in children with septic shock.

Every effort should be made to ensure an adequate airway, which may require periodic suctioning if the patient is unable to clear pooled secretions. Humidified oxygen in concentrations required to maintain an adequate partial pressure of oxygen should be provided early. The method of oxygen administration (e.g., mask, ventilator) depends on the clinical state of the patient. Intubation and assisted ventilation are indicated if the child shows evidence of impending respiratory failure.

ARDS, usually appearing within 2 days after the onset of shock, may complicate the respiratory and fluid management.⁹⁷ Pulmonary edema, atelectasis, decreased pulmonary compliance, and ventilation-perfusion abnormalities are some factors that can lead to inadequate oxygenation. Administration of excessive fluids may contribute to ARDS. The central venous pressure may remain normal despite the presence of pulmonary edema. Positive end-expiratory pressure, oxygen, and careful attention to cardiovascular parameters are the mainstays of therapy for ARDS.^{97,164,178}

The general supportive care of a child with septic shock includes attention to nutritional and metabolic requirements.¹⁷² Parenteral alimentation may be the only means by which to provide nutrition, although the optimal amount and composition of elemental nutrients for children with septic shock are unknown. Hypocalcemia should be corrected. Platelet transfusions or fresh-frozen plasma may be necessary to correct coagulopathies. Continuous venovenous hemofiltration with or without dialysis may be instituted for complications of renal failure, such as fluid overload with pulmonary edema or hyperkalemia. Children who have acute renal failure complicating severe septic shock have a significantly higher mortality rate than that of children without acute renal failure.¹⁶⁶

INVESTIGATIVE THERAPIES

Based on the evolving understanding of the pathophysiology of septic shock, many large, randomized, double-blind, multicenter trials have been conducted to assess the efficacy of agents that neutralize or counteract toxins or cytokines that are important in the evolution of septic shock. These immunomodulating strategies have been used on the basis of experimental data from animal studies. The conditions seen in experimental animal models of sepsis do not reflect the pathophysiologic situation seen in patients with severe sepsis or septic shock,

TABLE 62.4 Clinical Trials of Sepsis Medications in Adults

Trial	Agent Studied	Total Patients (N)	28-DAY MORTALITY (%)	
			Medications	Controls

TNF, Tumor necrosis factor.

however, which has led to many negative clinical trials (Table 62.4). One interesting newer approach is the development of endotoxin removal devices that are being evaluated to assess their potential as adjunctive measures to improve the outcome of patients with septic shock.⁵⁰

Intravenous immunoglobulin is recommended as adjunctive therapy for patients with toxic shock syndrome caused by either group A streptococcus or *S. aureus* that is not responding to aggressive therapy after several hours or after appropriate drainage of focal infections.¹⁶¹ The value of intravenous immunoglobulin in the treatment of septic shock caused by *S. aureus* infection but not associated with toxic shock syndrome has not been established.⁷⁶ Investigative antibodies such as tefibazumab, a monoclonal antibody directed against clumping factor A, an adhesin on the surface of *S. aureus*, has not been shown to improve the outcome of adults with *S. aureus* bacteremia.²³² Early phase 2 clinical trials of eritoran tetrasodium, a TLR4 antagonist, for the treatment of severe sepsis seemed promising; however, a recently completed phase 3 randomized trial did not improve the primary endpoint of 28-day all-cause mortality in 2000 adult patients with severe sepsis (http://www.ukmi.nhs.uk/applications/ndo/record_view_open.asp?newDrugID=4747).²⁰³

Plasmapheresis, exchange transfusions, and extracorporeal membrane oxygenation are heroic measures that seem to be beneficial in selected patients not responding to standard management.^{17,75,214} These procedures may be considered for such patients when, in the opinion of experienced clinicians, their use is justified and they are the last hope for a successful outcome.⁷¹

PROGNOSIS

The morbidity and mortality rates for septic shock in children vary with age, the presence or absence of underlying diseases, and the specific microorganisms responsible for the septicemic state. Dupont and Spink reported a 98% mortality rate in their series of children with septic shock and gram-negative bacteremia. Jacobs and colleagues reported a 9.8% case-fatality rate for otherwise normal children with septic shock. In the pediatric HA-1A study, the overall mortality rate for severe sepsis or septic shock was 31%. The overall mortality rate for children with meningococcal infection was 8% in a 10-center surveillance study. For the seven-state sepsis cohort, the overall mortality rate was approximately 10%. Much progress has been made in the treatment of sepsis and

septic shock since the report of Dupont and Spink was published. As with many infections, prevention is more desirable than is treatment. Careful attention given to sterile techniques for insertion and maintenance of intravascular or other lines and other procedures is crucial and may prevent some episodes of bacteremia and septic shock.

Petersdorf and Beeson⁸² in 1961 proposed that the term *fever of unknown origin* (FUO) be reserved for persons with an illness persisting for 3 or more weeks and accompanied by temperatures higher than 38.4°C (101.2°F) on at least several occasions. They further specified that the cause of the fever should remain undetermined after at least 1 week of investigation in the hospital. Although this definition was arbitrary, it was useful at that time, when many of the diagnostic tests now in routine use were unknown. The purpose of their precise definition was to explore the cause of fever in this select group of adult patients and to permit comparison of data from different investigations. This exacting definition probably never was applied rigorously in pediatric practice. In children, the term *fever of unknown origin* should be reserved for fever of at least 8 days' duration and for which no diagnosis is apparent after the initial workup in the hospital or as an outpatient.

Many investigators use the term *fever without source* (FWS) for fever of recent onset with no adequate explanation determined by the history or physical examination. The distinction between FUO and FWS is of more than academic interest for several reasons. First, although overlap exists, the differential diagnoses of these clinical conditions are distinct, and the most frequent causes of one can be different from the most frequent causes of the other. Second, a child with fever of recent onset generally warrants more immediate evaluation than does a child with FUO. The latter usually does not occur as an emergency and requires timely, but not urgent, diagnostic or therapeutic intervention. Third, although expectant antibiotic treatment of children with FUO generally is not indicated, expectant treatment of infants with FWS is recommended in certain cases.

FEVER WITHOUT SOURCE

A convenient definition of FWS is the occurrence of fever for 1 week or less in a child in whom a careful history and physical examination fail to reveal a probable cause of the fever. An estimated 14% of children with fever have no localizing signs or symptoms.¹⁰³ Most children with fever of recent onset have acute infectious diseases, the majority of which are self-limited.¹¹⁰ A few of these patients have serious acute infectious diseases, including meningitis, bacteremia, and urinary tract infection, and a very few have acute noninfectious diseases or chronic disorders. For example, an occasional patient with FWS is discovered to have a disorder such as heat illness, drug poisoning, Kawasaki disease, malignancy, or connective tissue disease. However, these disorders occur infrequently. A physician faced with a child with FWS should consider the possibility of a noninfectious cause or the onset of a chronic disease, but unless a clinical clue suggests one of these entities, investigation in this direction is not warranted.

Many children with FWS are in the prodromal stages of an acute infectious illness, and evidence of a specific infection, such as pharyngitis, otitis media, or pneumonia, develops within hours to days of first being evaluated by a physician. Fever can precede the appearance of specific signs and symptoms by as long as 3 days, as in measles, Rocky Mountain spotted fever, and leptospirosis. In some infections, such as roseola, viral hepatitis, infectious mononucleosis, typhus, and typhoid fever, the interval between the onset of fever and the appearance of specific findings often is more than 3 days.

Occult Bacteremia

One concern regarding a young child with FWS is the possibility that the child has occult bacteremia.⁴⁷ The patient does not appear ill, is judged clinically well enough to be managed as an outpatient, and does not have an infection commonly associated with bacteremia, such as pneumonia, but the blood culture yields pathogenic bacteria such as

Streptococcus pneumoniae, *Neisseria meningitidis*, *Haemophilus influenzae*, *Escherichia coli*, *Salmonella*, group A streptococcus, or *Staphylococcus aureus*. Before introduction of the pneumococcal conjugate vaccines, the incidence of occult bacteremia in children with FWS was approximately 3% to 5%.^{7,14,25,50,61,65,75,99,110} More recent data report an incidence of less than 1%, although this figure may vary depending on vaccine coverage rates in the population studied.^{2,3,31,46,85,90,97,103,108} A large prospective study of 3571 febrile children younger than 3 years of age found that no patients who had received at least one vaccination of heptavalent pneumococcal vaccine had pneumococcal bacteremia.²⁶ With the introduction of the 13-valent pneumococcal conjugate vaccine, further decreases in occult bacteremia caused by pneumococci are anticipated.^{27,45}

Historically occult bacteremia was found to occur more commonly in children with FWS than in febrile children of the same age with infections such as pharyngitis, otitis media, or upper respiratory tract infection. In the 1970s, investigators⁶⁵ reported the incidence of bacteremia in febrile children without an obvious source of infection to be 9.9%, as opposed to 3.3% in children with otitis media, upper respiratory tract infection, or a flulike syndrome. During the same era, Teele and colleagues⁹⁹ found a 3.9% incidence of bacteremia in children with FWS and a 1.5% incidence in comparably febrile children with otitis media or pharyngitis.

The risk for occult bacteremia developing in a child with FWS is age related, with the greatest risk occurring in the first few months of life. Numerous studies have demonstrated a higher risk for bacteremia or other serious bacterial infections in febrile infants younger than 3 months old.^{63,65,89,99} In a group of children with clinically unsuspected meningococcemia, all 12 patients who initially looked well enough to be treated as outpatients were younger than 24 months of age.³⁴ In the 1990s, Bonadio and colleagues²¹ found the incidence of positive bacterial cultures to be 12% in febrile infants younger than 4 weeks and 6% in those between 4 and 8 weeks of age. A more recent retrospective study of bacteremia in infants 1 week to 3 months of age found 2% of all blood cultures were positive for pathogens.⁴¹ The risk for having occult bacteremia and other serious bacterial infections increases with the severity of fever.⁶⁶ In a prospective study in which blood was obtained for culture from all febrile children younger than 2 years seen in a walk-in clinic, no positive blood cultures were found in 44 children with FWS and rectal temperatures lower than 38.9°C (102°F), whereas five (3.9%) positive blood cultures were found in 129 children with FWS and rectal temperatures of 38.9°C (102°F) or higher.^{87,99} Other studies have reported similar findings.^{14,63,90} Several series of children with fevers of 41°C (105.8°F) or higher found a relatively high prevalence of bacteremia and other serious bacterial infections, especially meningitis and pneumonia.^{20,63,87} However, even in this group of children with very high fever, most of those older than 2 or 3 months of age who looked well did not have a serious bacterial infection.

The white blood cell (WBC) count has been studied extensively as a potential tool in the diagnosis of occult bacteremia. On the basis of a study of hospitalized children, Todd¹⁰⁰ reported that the absolute number of polymorphonuclear leukocytes and the absolute number of nonsegmented polymorphonuclear leukocytes were more sensitive than was the total WBC count, the percentage of polymorphonuclear leukocytes, or the percentage of nonsegmented polymorphonuclear leukocytes. However, whether information based on hospitalized children—presumably all of whom had serious localized infections or looked ill enough to warrant hospitalization—can be applied to children with FWS who look well enough to be treated on an ambulatory basis is questionable.

Considerable debate continues over the usefulness of the WBC count in febrile children evaluated in the outpatient setting. McCarthy and

associates⁶⁶ concluded that a WBC count of 15,000/mm³ or greater was helpful in identifying patients at greatest risk for the development of bacteremia. Dershewitz³⁵ found a direct relationship between the total leukocyte count and the prevalence of bacteremia and stated that “knowledge of the count was a helpful but limited predictor of patients with positive blood cultures.” Other investigators reported that the incidence of bacteremia increased with an increased WBC count⁹⁰ and that bacteremia most commonly occurred in patients with counts of 20,000/mm³ or higher.⁷¹

Other studies have examined the utility of the WBC count specifically in children with FWS who look well enough to be treated on an outpatient basis. One such study found a sensitivity of 1.0 and a positive predictive value of 0.11 for a total WBC count of 15,000/mm³.⁹⁹ Using a WBC count of 20,000/mm³ would have decreased the sensitivity to 0.4 while increasing the positive predictive value to only 0.13. In another series, the sensitivity for a WBC count of 15,000/mm³ was 0.87, with a specificity of 0.73.¹⁴ Although a total WBC count of 15,000/mm³ does not accurately predict which child is or is not bacteremic, it is helpful in dividing the population of children with FWS into high- and low-risk groups.^{15,46} However, the value of the 15,000/mm³ level has been substantially reduced in the studies conducted since the pneumococcal conjugate vaccine was introduced.

Some investigators have found the erythrocyte sedimentation rate to be no more useful than the WBC count in predicting bacteremia in ambulatory febrile patients.⁶⁶ Others have reported that the serum concentration of C-reactive protein may be more accurate than the complete blood count or erythrocyte sedimentation rate in distinguishing bacterial from viral infections.^{64,81} However, recent studies reported conflicting data regarding the utility of the C-reactive protein test in screening children 3 to 36 months old for occult bacteremia.^{48,88,95} An elevated serum procalcitonin level has been found by some investigators to be at least as sensitive and specific as C-reactive protein in predicting serious bacterial infection in children with fever and no localizing signs.^{5,56,86,113} A meta-analysis of 881 children from developed countries with FWS found that procalcitonin in addition to WBC count and C-reactive protein tests was more accurate for detecting early meningococcal disease than WBC and C-reactive protein testing alone.¹⁷

Other hematologic findings that suggest bacteremia include thrombocytopenia,³⁰ Döhle inclusion bodies, toxic granulations, and vacuolization of neutrophils. In one study, peripheral blood smears of children younger than 24 months with acute febrile illnesses were reviewed the following day by a single investigator to determine whether vacuolization and toxic granulations were present; when both abnormalities were present, the positive predictive value for bacteremia was 0.76.⁵⁸ The presence of these findings should be considered when estimating the risk for bacteremia.^{1,30,74}

Several studies have examined the response to acetaminophen and found no difference in the rate of reduction of temperature or improvement in clinical appearance between bacteremic and nonbacteremic children.^{10,101,112} Mazur and associates,⁶² however, found that febrile children aged 2 months to 6 years who did not respond to a dose of acetaminophen by a reduction in temperature of at least 0.8°C in 2 hours had a statistically significant increased risk for having occult bacteremia in contrast to those who did respond.

The most important aspects of assessment of a febrile child are a careful history and physical examination. Laboratory data are secondary and should be ordered on the basis of the clinical assessment. By definition, a child with FWS has no localizing signs to explain the fever or indicate a site of infection. Many physicians suggest that a general impression can indicate whether the child has occult bacteremia. Some physicians have suggested that careful clinical judgment, based on extensive experience, can identify most, if not all, children with serious illnesses.^{19,79} McCarthy and colleagues,^{65,67-69} in a series of carefully designed studies, elucidated the variables of history and observation that were most useful in assessing febrile children. They found that observation of the variable *playfulness* had the strongest correlation with overall assessment.⁶⁸ However, they observed that even an experienced attending pediatrician could identify only 57% of seriously ill children by initial impression before performing a full physical examination. Dershewitz³⁵ found that private pediatricians were no more accurate

than pediatric residents in identifying children with occult bacteremia and that, in the private office, pediatricians were no better at predicting bacteremia in familial patients than in first-time patients.

In a study of 292 consecutive febrile children seen in an emergency department, Waskerwitz and Berkelhammer¹⁰⁵ identified a subgroup of patients who had no localizing signs and who looked so well that they were predicted not to have bacteremia. The physicians were assisted in their assessment by a functional scale that gave 0 to 2 points for the child's eating, drinking, sleeping, and play activities, with a best possible score of 8. The group of patients who had functional scores of 5 or greater, with no localized infection and predicted clinically not to have bacteremia, were free of bacteremia, whereas 14 of 202 patients with functional scores of 4 or less were bacteremic. In this study, the physicians were not able to identify which patients had bacteremia and which did not; rather, they were able to identify one subgroup at high risk for having bacteremia and another at very low risk. Teach and Fleisher⁹⁸ found that although Yale Observation Scale scores were higher in patients with bacteremia than in those without, the difference was not clinically useful in detecting bacteremia in well-looking febrile children without a discernible focus of infection. The clinician's overall assessment of the degree of illness of the child appears to be a valuable but not infallible tool in estimating the risk for occult bacteremia in children with FWS.

Clinical Management of Fever Without Source

The clinician should not be dogmatic about the management of children with FWS. One reasonable approach, based on a careful history, thorough physical examination, and overall clinical impression, is to classify these children as being at low or high risk for the presence of occult bacteremia and other serious bacterial infections. For the low-risk group, no laboratory investigation is required routinely. For the high-risk group, a complete blood count and blood culture should be obtained, especially in young infants and children who are incompletely immunized. Many studies have shown that the most common serious bacterial infection in children with FWS is urinary tract infection.^{4,103,106} Therefore, urinalysis and urine culture should be performed in febrile infants and children younger than 24 months of age. Lumbar puncture and chest radiography are considered on an individual basis. If the patient appears ill, admission to the hospital may be justified even if all test results are negative. When high-risk children look well enough to be sent home, they are reasonable candidates for expectant antibiotic therapy pending the outcome of blood and urine cultures. For patients clinically considered to be at moderate risk (not clearly high or low risk), the physician has the option of obtaining a WBC count and using the results to decide whether to obtain blood and urine for culture and prescribe antibiotics expectantly.

Table 63.1 lists risk factors for the development of occult bacteremia. Current information is not sufficient to warrant the use of scoring systems except as part of investigational series. In the final analysis, the clinician's judgment, taking into account all available clinical and laboratory data about each patient, is the guide to selecting which children require a diagnostic workup and expectant therapy with antibiotics.

If the physician elects to prescribe antibiotics while awaiting the results of blood culture, such antibiotic therapy should provide adequate coverage for *S. pneumoniae*, *N. meningitidis*, and *H. influenzae*, although the frequency of *H. influenzae* and *S. pneumoniae* has decreased dramatically with current immunization practice, and *N. meningitidis* is uncommon. A single injection of ceftriaxone 50 to 75 mg/kg given while awaiting the results of blood culture has been successful in resolving fever, clearing bacteremia, and preventing meningitis and was found to be superior to oral regimens in several series.^{13,16,40} Children with a positive blood culture should be recalled for re-evaluation even if they are afebrile.⁸ Children who have been immunized against both *H. influenzae* and *S. pneumoniae* should be considered to be at relatively low risk for the development of occult bacteremia and may require less workup unless they appear ill or have a very high fever.

Infants younger than 90 days pose a special problem because they have an increased risk for developing a serious bacterial infection, clinical evaluation is more difficult, and a broader spectrum of invading organisms (e.g., group B streptococcus, *E. coli*, and *Listeria monocytogenes*) exists. Baker and coworkers⁹ showed the safety of managing selected

TABLE 63.1 Risk Factors for Occult Bacteremia

Factor	High Risk	Low Risk
Age	≤3 months	>3 months
Immunization status ^a	Incomplete	Complete
Magnitude of fever	≥40°C (104°F)	≤39.4°C (103°F)
White blood cell count	≥15,000/mm ³	<15,000/mm ³
Peripheral blood smear	Toxic granulation or vacuolization of polymorphonuclear leukocytes, thrombocytopenia	Unremarkable
Underlying chronic disorder	Sickle-cell disease, immunodeficiency, malnutrition	None
History of contact with bacterial disease	Contact with <i>Neisseria meningitidis</i> or <i>Haemophilus influenzae</i>	None
Clinical appearance	Appears ill, toxic, or unhappy; inconsolable; irritable or lethargic; not eating or drinking enough	Looks well, playful, eating normally, not irritable

^aVaccination status is incomplete if the child has received fewer than three doses of *Haemophilus influenzae* vaccine and fewer than three doses of conjugated pneumococcal vaccine and is complete if the child received at least three doses of each vaccine.

low-risk infants (i.e., normal WBC count, urinalysis, lumbar puncture, and chest radiograph, and, if diarrhea was present, negative smear for fecal leukocytes) 30 to 90 days of age on an outpatient basis without antibiotics. Jaskiewicz and coworkers⁵² found the Rochester criteria (WBC count of 5000 to 15,000/mm³, band count <1500/mm³, spun urine specimen <10 WBCs/high-power field, stool specimen [if diarrhea] <5 WBCs/high-power field) to have a 98.9% negative predictive value in well-appearing, previously healthy infants younger than 90 days with no focal infections. One reasonable practice guideline for managing infants with FWS is to hospitalize and treat all who appear toxic and all younger than 28 to 30 days. Those between 30 and 90 days of age can be managed as outpatients if they look well and the blood count, urinalysis, and cerebrospinal fluid analysis (if empiric antibiotics are to be prescribed) are within normal limits.^{11,12}

FEVER OF UNKNOWN ORIGIN

The exact definition of FUO is a subject of considerable disagreement, and series in the pediatric literature differ in their criteria for inclusion. Brewis²² defined FUO in children as a temperature of 38.3°C (101°F) or higher for 5 to 7 consecutive days without localizing signs or symptoms. In sharp contrast, McClung⁷⁰ and Lohr and Hendley⁵⁹ considered children with fever for at least 3 weeks on an outpatient basis or 1 week in the hospital to have FUO. Pizzo and associates,⁸⁴ however, required only that the fever be present for 2 weeks, with no distinction made between outpatient or in-hospital status. A reasonable working definition of FUO for clinical purposes is the presence of fever for 8 or more days in a child for whom a careful and thorough history, physical examination, and preliminary laboratory data fail to reveal a probable cause of the fever.

Most cases of FUO in children are caused by relatively common diseases.³⁸ In four series of FUO totaling 418 children, only five patients would be considered to have rare disorders (i.e., Behçet syndrome, ichthyosis, variant of “blue diaper” syndrome, diencephalic seizure disorder, and “possible chronic lead and/or arsenic intoxication”).^{22,59,70,84} The adage that FUO is more likely to be caused by an unusual manifestation of a common disorder than by a common manifestation of a rare disorder certainly is true in pediatrics. The three most common discernible causes of FUO in children, in order of decreasing frequency, are infectious diseases, connective tissue diseases, and neoplasms. In approximately 10% to 20% of cases, a definitive diagnosis never is established.

In the United States, the systemic infectious diseases diagnosed most frequently in children with FUO include tuberculosis, brucellosis, tularemia, salmonellosis, cat-scratch fever and infections caused by rickettsia, spirochetes (e.g., leptospirosis), Epstein-Barr virus, cytomegalic inclusion virus, human immunodeficiency virus (HIV), hepatitis viruses, and other viruses. The most common causes of localized infection are upper respiratory tract infections (e.g., sinusitis, otitis, tonsillitis), urinary tract infection, osteomyelitis, and occult abscesses, including hepatic and pelvic abscesses.

The connective tissue disease most commonly manifested as FUO in children is juvenile idiopathic arthritis, which accounts for more

than 90% of connective tissue diseases in most series, followed by systemic lupus erythematosus and then by undefined vasculitis.^{59,70,73,84} Frequently a definitive diagnosis of juvenile idiopathic arthritis can be made only after an extended period of observation because physical examination may yield few findings and the results of specific serologic studies generally are normal or negative.

Malignancy is a less frequent cause of FUO in children than in adults and usually is the third-largest group, after infectious diseases and connective tissue diseases. Malignancy accounted for 7% of FUO cases in the series reported by Pizzo and associates⁸⁴ and for 13% in the Lohr and Hendley⁵⁹ series. Leukemia and lymphoma are responsible for most cases of cancer manifested as FUO in children. Other tumors less commonly reported as causing FUO include neuroblastoma, hepatoma, sarcoma, and atrial myxoma.

The prognosis for children with FUO is better than that for adults, and most children with FUO have treatable or self-limited disease. Historically mortality rates for children with FUO were 6% to 9%.^{59,84} However, more contemporary studies indicate that mortality is quite low.⁸⁰

Diagnostic Approach to a Child With Fever of Unknown Origin

A child with FUO may be admitted to the hospital for more than simply laboratory investigation. Hospitalization provides an opportunity to observe the child, repeat the history and physical examination, analyze all available data, and investigate every potential diagnostic lead. In the Lohr and Hendley⁵⁹ series of 54 children with FUO, an incomplete history delayed establishing the diagnosis in nine cases, and physical findings that were ignored delayed rendering the diagnosis in four cases. In McClung's report⁷⁰ of 99 pediatric cases of FUO, errors in the history or physical examination obscured the correct diagnosis for at least 10 patients. Failure to use existing laboratory data correctly is another common factor preventing early determination of the diagnosis in children with FUO.^{59,84}

Clinical Evaluation

The first and most important step in the diagnostic workup of a child with FUO is obtaining a complete and detailed history and conducting a physical examination. The clinical evaluation must be thorough and careful, and it must be repeated frequently. Often a patient or parent eventually recalls information that was omitted or forgotten when the initial history was obtained. Physical findings change, and abnormalities not originally present can appear subsequently. Lohr and Hendley⁵⁹ noted that in more than 25% of children admitted to the hospital with FUO, significant physical findings developed that were not present at the time of admission.

A detailed history should be obtained regarding contact with infected or otherwise ill persons and any exposure to animals, including pets and wild animals. The number of children with zoonotic infections is increasing each year. History of a cat scratch or exposure to kittens may be a clue for *Bartonella henselae*. Immunization of domestic animals such as the dog against leptospirosis can prevent canine disease, but it

does not prevent carriage, excretion, and transmission of this infection. A history of travel extending back to birth must be elicited. Reemergence of histoplasmosis, coccidioidomycosis, blastomycosis, leishmaniasis, or malaria years after visiting or living in an endemic area can occur. Inquiring about prophylactic immunizations, precautions taken against the ingestion of contaminated food or water, and malarial prophylaxis is important. Questioning should include the possibility that rocks, soil, or artifacts from geographically distant regions may have been brought into the home, as well as the possibility that contact with persons who have visited distant countries has occurred. Even contact with insects can be important. Tick bites can be a clue to Rocky Mountain spotted fever or tick-borne relapsing fever. North American mosquitoes and some ticks carry a variety of arboviruses.

The physician should determine whether the patient has eaten game meat, raw meat, or raw shellfish. A history of pica should be sought routinely. Ingestion of dirt can suggest a diagnosis of visceral larva migrans, toxoplasmosis, or other infectious diseases. A detailed history regarding all medications, including topical agents and non-prescription items, must be elicited. Any history of surgical procedures should be explored.

Questions designed to determine the genetic or ethnic background of the patient can reveal information that specifically suggests or largely excludes diagnoses such as nephrogenic diabetes insipidus (found in Ulster Scots), familial Mediterranean fever (found in Armenians, Arabs, and Sephardic Jews), familial dysautonomia (found in Jews), and Kikuchi-Fujimoto disease, a benign and self-limited histiocytic necrotizing lymphadenitis (found mostly in young Asian females and characterized by fever, lymphadenopathy, and malaise).

The history should be exacting regarding the duration, height, and pattern of the fever, as well as the circumstances under which temperature elevation occurs, whether the child appears ill or any signs or symptoms develop, and how well the fever responds to antipyretic drugs. A history of "fever" occurring only after exercise or late in the afternoon can indicate parental concern about normal variations in body temperature. A history of high fever occurring in the absence of malaise or other generalized signs can be a clue to factitious fever. The physician also should obtain a careful history regarding how well the fever has been documented. Has a thermometer been used, by whom, and in whose presence? A history of sweating and heat intolerance can indicate hyperthyroidism, whereas a history of heat intolerance with the absence of sweating can be a clue to ectodermal dysplasia.

Several investigators found that neither the pattern of fever nor its duration was useful in pointing to or establishing a diagnosis in children with FUO.^{59,84} However occasionally the character of the fever can be helpful. *Intermittent fever* is characterized by a return of temperature to normal at least once daily. If the peak of fever is high and the rate of defervescence quick, this pattern often is referred to as *hectic* or *spiking*. Intermittent fevers suggest pyogenic infections but also occur with tuberculosis, lymphoma, and juvenile idiopathic arthritis. In *remittent fever*, the temperature fluctuates but does not return to normal. A *sustained fever* pattern is characterized by persistent fever with little or no fluctuation and can occur in typhoid fever or typhus. Antipyretic agents can make a remittent or sustained fever appear intermittent. *Relapsing fever* refers to a pattern in which the patient is afebrile for 1 or more days between episodes of fever and can be seen with malaria, rat-bite fever, infection with *Borrelia*, and lymphoma. Recurrent episodes of fever of more than a year's duration can suggest metabolic defects, central nervous system abnormalities in temperature control, and immunodeficient states.

The general activity and appearance of the patient should be observed, vital signs checked, and growth parameters measured. Weight loss is an important, though nonspecific, finding. Impairment of linear growth or short stature can be a clue to inflammatory bowel disease, an intracranial lesion involving the pituitary gland, or a long-standing chronic disease. Examining the patient during an episode of fever to observe the presence or absence of sweating, the effect of the fever on the heart and respiratory rate, the presence or absence of malaise or other symptoms, and the appearance of "toxicity" is helpful. The rash of juvenile idiopathic arthritis characteristically is evanescent and may be present only during periods of temperature elevation.

Some special aspects of the physical examination merit mention. Hypohidrosis, anomalous dentition, and sparse hair, particularly involving the eyebrows and eyelashes, suggest anhidrotic ectodermal dysplasia. Palpebral conjunctivitis can be a clue to the presence of infectious mononucleosis, Newcastle disease, or lupus erythematosus, whereas predominantly bulbar conjunctivitis can suggest leptospirosis or Kawasaki disease. Phlyctenular conjunctivitis can signal tuberculosis.

Absence of the pupillary constrictor response can be caused by a deficiency of the constrictor sphincter muscle of the eye. This muscle, derived from ectoderm rather than mesoderm, develops embryologically at the same time that hypothalamic structures and function are undergoing differentiation. Absence of this muscle can suggest that the elevation in temperature is the result of hypothalamic or autonomic dysfunction. Careful funduscopic examination can disclose evidence of miliary tuberculosis, vasculitis, or toxoplasmosis. Lack of tears, absence of corneal reflexes, and a smooth tongue with absence of the fungiform papillae suggest familial dysautonomia.

Purulent or persistent nasal discharge can be a sign of sinusitis. The physician should palpate for tenderness over the sinuses.

Hyperemia of the pharynx, even in the absence of exudate or specific symptoms, can be a clue to the diagnosis of infectious mononucleosis, cytomegalovirus, toxoplasmosis, tularemia, or leptospirosis. Gingival hypertrophy or inflammation and loosening or loss of teeth can indicate leukemia or Langerhans cell histiocytosis.

The bones and muscles should be palpated carefully. Tenderness over a bone can be found in cases of osteomyelitis or marrow invasion by neoplastic disease. The appreciation of a new heart murmur may result from infective endocarditis. Muscle tenderness can be associated with trichinosis, dermatomyositis, polyarteritis, or various arboviral infections.

The search for skin lesions and rash must be careful, extensive, and repeated. Petechiae can indicate endocarditis or other sources of bacteremia but also can occur with viral and rickettsial infections. A seborrheic rash can be a sign of histiocytosis. A small papule present for more than a week may be the inoculation site for cat-scratch disease.

A careful rectal examination can reveal pararectal tenderness or a mass indicative of a pelvic abscess or tumor. A test for occult blood should be performed on stool. Examination of the external genitalia should be completed on patients of all ages, and sexually active adolescent females should undergo a pelvic examination.

Laboratory Evaluation

The extent of laboratory investigation depends on the age of the patient, duration of the fever, and history and physical examination findings. Laboratory studies should be directed, as much as possible, toward the most likely diagnostic possibilities. The tempo of the diagnostic evaluation should be adjusted to the severity of the illness. In a critically ill child, speedy evaluation is important. If the patient is less severely ill, however, the evaluation can proceed more slowly; sometimes the fever can disappear without apparent explanation before a definitive diagnosis can be established and any invasive diagnostic procedures have been undertaken.

A complete blood count and careful examination of the peripheral smear are indicated for all patients. Anemia, thrombocytosis, and thrombocytopenia should be noted. Although mild or moderate changes in the total WBC or differential count usually are of no help, in some series, children with more than 10,000 polymorphonuclear leukocytes or 500 nonsegmented neutrophils/mm³ were found to have a greater likelihood of having a serious bacterial infection.¹⁰⁰ Atypical lymphocytes generally indicate viral infection, whereas bizarre or immature forms can suggest leukemia. Although the erythrocyte sedimentation rate and C-reactive protein are of no specific diagnostic value, they are a general indicator of inflammation and can help in ruling out factitious fever, determining the need for further evaluation, and monitoring the progress of the disease process.

Blood should be obtained from all patients for aerobic and anaerobic culture. In select cases, media appropriate for the isolation of *Francisella* organisms, *Leptospira*, and *Spirillum* also should be used.

Urine analysis and culture should be completed for all patients. In one series of FUO in children, failure to perform urinalysis and failure

to investigate pyuria adequately were the most common laboratory errors.⁷⁰ Radiographic study of the urinary tract, however, should be performed only when indicated.

All patients should undergo radiographic examination of the chest. Diagnostic imaging of the nasal sinuses, mastoids, and gastrointestinal tract is performed initially only for specific indications but may be done eventually in all children whose fever persists without explanation for a long period. Persistent fever and elevation of the erythrocyte sedimentation rate or C-reactive protein, with or without anemia, abdominal complaints, anorexia, and weight loss, are sufficient indications for radiographic study to evaluate for inflammatory bowel disease.

All patients should have an intradermal tuberculin skin test. Control skin tests with antigens such as *Candida* are of limited value because the anergy may be specific for tuberculosis rather than universal for all skin-testing materials.^{60,72,76,77} A positive control test result and negative tuberculin test result do not rule out tuberculosis.

Bone marrow examination is most useful in diagnosing cancer (especially leukemia), histiocytic disorders, and hemophagocytic disease. It is less useful in determining infection. Hayani and associates⁴⁴ reviewed the results of 414 bone marrow examinations for FUO in children. In only one case was an organism (*Salmonella* group D) recovered from the marrow that also was not recovered from blood or another source. Noninfectious causes of FUO were found in 8% of specimens: malignancy (6.7%), hemophagocytic lymphohistiocytosis (0.7%), histiocytosis (0.5%), and hypoplastic anemia (0.2%). In most of these cases, the diagnosis had been suspected clinically before the bone marrow was examined.

Patients should undergo a serum test for HIV infection. Other appropriate serologic tests can help establish a diagnosis of cat-scratch disease, brucellosis, tularemia, Epstein-Barr virus infection, cytomegalovirus infection, other viral infections, toxoplasmosis, and certain fungal infections.

Hepatic enzymes and serum chemistry, including electrolytes, urea nitrogen, and creatinine, should be determined in all patients. Serum antinuclear antibody should be measured in those older than 5 years if family history is significant or clinical suspicion warrants it. Serum hepatitis antigens, electrocardiography, electroencephalography, echocardiography, and stool culture and examination for ova and parasites generally should be performed in selected cases. Other tests to be considered for individual patients include ophthalmologic examination by slit lamp, radiographic bone survey, technetium bone scan, abdominal imaging by ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI).^{24,83} CT scanning and indium-111 scanning³⁹ can detect inflammatory lesions and tumors. Such scanning procedures offer a relatively noninvasive technique for screening patients with FUO for a variety of disorders. Steele and associates⁹⁴ found that radionuclide scans seldom led to unsuspected diagnoses in children and suggested that they not be used indiscriminately. Gallium scanning has been helpful in diagnosing adult patients with FUO⁴³ but is not generally recommended in children. Recent evidence suggests that (18)F fluorodeoxyglucose positron emission tomography (FDG PET) imaging may be useful in select adults and children with FUO in whom the etiology of fever remains elusive despite thorough physical examination, laboratory evaluation, and basic imaging techniques.^{53,92} FDG PET may be able to detect causes of FUO such as infection, tumor, and noninfectious inflammation because they all exhibit hypermetabolism of glucose. Identification of abnormalities using FDG PET could guide the next steps in clinical decision making to make the diagnosis. More invasive testing such as lymph node biopsy, liver biopsy, and exploratory laparoscopy are reserved for patients with evidence of involvement of these organs.

In general, antibiotics or other medications should not be administered empirically as a diagnostic measure in children with FUO. Exceptions include the use of nonsteroidal agents in children with presumed juvenile idiopathic arthritis and the use of antituberculosis drugs in critically ill children thought to have disseminated tuberculosis. Empiric trials of broad-spectrum antibiotics generally do more to obscure than illuminate the etiology of FUO and can mask or delay establishing the diagnosis of infections such as meningitis, parameningeal infection, endocarditis, or osteomyelitis.

Examples of disorders that can be manifested as FUO in children are listed in Box 63.1. A few of these disorders are discussed briefly in the following sections.

Infectious Causes of Fever of Unknown Origin

Infectious causes of FUO can be divided into systemic and localized. Immunodeficiency states may be considered under the general classification of infections.

Generalized Infections

Brucellosis. The manifestation of this disease as FUO is explained by the nonspecific symptoms that it engenders and by the chronicity of untreated infection. Many physicians, particularly in urban areas, tend to ignore the possibility of this disease and neglect to inquire about a history of exposure to animals or animal products, especially the consumption of unpasteurized goat's milk cheese (see Chapter 128).

Cat-scratch disease. During recent years, many children with FUO have proved to be infected with *B. henselae*. Cat-scratch disease is one of the most common causes of FUO in patients seen at the infectious disease service at Texas Children's Hospital in Houston.⁶ Most of the children with this manifestation of cat-scratch disease have hepatosplenic involvement. Jacobs and Schutze⁴⁹ reported that *B. henselae* infection was the cause of 4.8% of all cases of FUO at the Arkansas Children's Hospital and 10.9% of the cases of FUO caused by infection. *B. henselae* infection is best diagnosed by serologic evaluation (i.e., immunofluorescence assay that detects serum antibody to *B. henselae*). Biopsy of lesions (e.g., lymph nodes, liver, bone marrow) may allow visualization of bacilli with the Warthin-Starry silver stain; however, this finding is not specific for *B. henselae*. Management of patients with cat-scratch disease is primarily symptomatic because the disease usually is self-limited. Antimicrobial therapy can be helpful in acutely or severely ill patients, especially those with hepatosplenic disease. Several oral antimicrobial regimens (rifampin, trimethoprim-sulfamethoxazole, and azithromycin) and parenteral gentamicin have been used successfully for the treatment of this disease. Specifically rifampin 20 mg/kg per day in two divided doses for 14 days has been particularly efficacious.⁶ However, the optimal duration of therapy is not known.

Leptospirosis. Leptospirosis is caused by a single family of organisms composed of multiple serotypes; it is one of the most widespread zoonoses in the world. Transmission of infection from animal to human can occur by direct contact with the blood, tissue, organs, or urine of infected animals or indirectly by exposure to an environment that has been contaminated by leptospire. The organism also can be acquired from soil or from fresh water after ingestion. Reports indicate that leptospirosis is not a rare disease, that many infections are not associated with occupational exposure, and that urban and suburban cases are becoming more prevalent.¹¹⁴ Clinical manifestations of leptospirosis usually are not specific. A variety of laboratory aids are available, but specimens must be collected and handled properly. In some cases, establishing a definitive diagnosis may be impossible; negative cultures or failure to demonstrate a rise in antibody titer does not exclude the possibility that the patient has active infection because the organism may not be present in the specimens that have been cultured, the antibody titer may have peaked before an acute-phase specimen was collected, and antibiotic therapy may suppress the development of positive titers or delay their appearance (see Chapter 142).

Toxoplasmosis. Toxoplasmosis should be considered in any child with persistent fever. Cervical or supraclavicular adenopathy is present in most cases, but occasionally fever is the only manifestation. The diagnosis is established by demonstration of a rising serologic titer; antibody to *Toxoplasma gondii* is so prevalent that demonstration of a high titer alone is not diagnostic of acute infection. Demonstration of *Toxoplasma* in tissue sections or body fluid is highly suggestive, although the organism can persist in tissue for years. Isolation of the parasite is not absolutely diagnostic of recent infection (see Chapter 224).

Malaria. Malaria also should be considered in children with FUO. In addition to fever, splenomegaly usually is present. A history of travel to endemic areas should be sought, although malaria has occurred in patients who never traveled outside the United States. Disease can occur even in persons who have taken antimalarial drugs when they visited

the endemic region. A delay of several months can occur between the development of infection and the onset of symptoms. The infection can be transmitted from a person who has visited an endemic area to one who has not when an appropriate mosquito vector is present. Malaria also can be acquired by blood transfusion or by the use of needles and syringes contaminated by the parasite. Demonstration of malarial organisms on appropriately stained thin or thick smears of blood is diagnostic (see Chapter 220).

Salmonellosis. *Salmonella* organisms are contaminants in many food products. In view of the nonspecific signs and symptoms with which salmonellosis can occur, its association with FUO in children is not surprising. Repetitive blood and stool cultures are most helpful in establishing a diagnosis (see Chapter 111).

Tuberculosis. Tuberculosis is an important cause of FUO in children, as well as in adults. Nonpulmonary tuberculosis is manifested as FUO more frequently than is pulmonary tuberculosis, which usually is evident on routine chest radiographs. FUO occurs most commonly with disseminated tuberculosis or infection of the liver, peritoneum, pericardium, or genitourinary tract. Active disseminated tuberculosis has been well documented in children with negative results on chest radiography and tuberculin skin tests.^{77,96} Negative interferon- γ release assay results also may occur.³² A high index of suspicion and a careful history of possible contacts are important to make the diagnosis. Funduscopic examination can reveal choroid tubercles. Liver and bone marrow frequently are involved in children with miliary tuberculosis; liver biopsy specimens and bone marrow aspirates should be obtained and processed for

morphologic evaluation and culture. If the chest radiograph yields abnormal results, cultures of gastric aspirates, sputum, or both should be obtained. Because nontuberculous mycobacteria (i.e., atypical organisms) are present in the gastric contents of normal individuals, demonstration of acid-fast organisms on smears of gastric secretion does not necessarily indicate disease. Rarely a patient with tuberculous pericarditis has fever, weight loss, and weakness but no precordial pain or other specific cardiac complaints. Disseminated infection with atypical mycobacteria generally is seen in patients infected with HIV (see Chapter 96) or those with other immunodeficiencies.

Tularemia. Generally failure to consider tularemia in children with FUO may be attributed to a lack of appreciation of the many sources of infection and the various routes of inoculation. The organism can be acquired from contact with a variety of animal species, as well as from ticks, mosquitoes, lice, fleas, flies, and contaminated water. The organism can penetrate mucous membranes and broken or unbroken skin, or it can be inhaled or swallowed. Patients and parents should be questioned about animal contact and the ingestion of rabbit or squirrel meat (see Chapter 132).

Viral infections. Infection by most viruses produces an illness that is relatively brief. Exceptions to this rule can include infections by adenovirus, cytomegalovirus, Epstein-Barr virus, hepatitis viruses, and certain arboviruses. In all of these diseases, symptoms are extremely variable, and signs and symptoms frequently are nonspecific. The diagnosis can be established by appropriate cultures and serologic studies (see Chapter 253).

Immunodeficiency. A variety of congenital and acquired immunodeficiency states can manifest as FUO. Patients with immunoglobulin deficiencies (e.g., Bruton agammaglobulinemia) may have a long history of recurrent fever, with or without evident infection, whereas patients with abnormalities in lymphocyte function are more likely to have prolonged fever caused by persistent viral or parasitic infection.

Localized Infections

Bacterial endocarditis. Infective endocarditis is an infrequent cause of FUO in children. Acute bacterial endocarditis tends to be fulminant, but the subacute form begins insidiously, generally at the site of a preexisting cardiac lesion. Subacute bacterial endocarditis is a rare occurrence in infants and increases in frequency with advancing age. The organisms most commonly encountered are viridans streptococci, enterococci, *S. aureus*, and *Staphylococcus epidermidis*. The absence of a cardiac murmur does not exclude the possibility of endocarditis, especially when the infection is limited to the right side of the heart. Endocarditis also can occur in the absence of positive blood cultures, particularly in association with the following factors: use of antibiotics for an undefined febrile illness, right-sided cardiac lesions, prolonged duration of disease, infection by unusual organisms such as *Brucella* or *Coxiella burnetii*, and inadequate culture methods for the detection of infection with anaerobic organisms. Frequently associated laboratory findings include anemia, leukocytosis, and an elevated erythrocyte sedimentation rate. Several blood cultures (aerobic and anaerobic) of adequate volume should be obtained before starting antibiotics. Echocardiography can reveal vegetations, but negative results do not rule out endocarditis (see Chapter 26).

Bone and joint infections. Infections of bones and joints usually can be diagnosed clinically but occasionally are manifested as FUO. This manifestation occurs commonly in young children who cannot explain where they hurt and is more likely to occur with osteomyelitis than with septic arthritis. Infection of the pelvic bones is implicated most often in this regard. Radioisotopic bone scan and MRI are more sensitive than are plain radiographs of the bones (see Chapters 55 and 56).

Intraabdominal abscesses. Subphrenic, perinephric, and pelvic abscesses may be manifested as FUO. A history of previous intraabdominal disease or abdominal surgery or a history of vague abdominal complaints should heighten suspicion of an intraabdominal collection of pus. The organisms involved most commonly are *S. aureus*, streptococci, *E. coli*, and anaerobic flora. Fever may be the only sign of a pelvic, perinephric, or psoas abscess. Urinalysis generally yields normal results, but the mass can be demonstrated by ultrasound examination, CT, or MRI.

Liver abscess and other hepatic infections. Pyogenic liver abscesses are encountered most frequently in immunocompromised pediatric patients but can be seen in otherwise normal children.⁵⁵ In some patients, persistent fever is the only finding. Blood cultures usually are sterile, and serum levels of liver enzymes generally are close to or within normal limits. Many patients have hepatomegaly and right upper quadrant abdominal tenderness. The diagnosis can be established by examination of the liver by ultrasonography, CT, or MRI. Bacterial hepatitis and bacterial cholangitis can occur in the absence of jaundice and other specific signs of liver dysfunction.^{107,111} Granulomatous hepatitis is not a specific disease but rather a syndrome characterized by granuloma formation within the liver. A specific cause cannot be determined in every case. Although most reported cases have been in adults,⁹¹ pediatric cases do occur, particularly with Epstein-Barr virus infection and with cat-scratch disease. The diagnosis can be made by ultrasound or other diagnostic imaging (see Chapter 49).

Upper respiratory tract infections. Frequently, infections of the upper respiratory tract and related organs manifest as FUO.^{59,70,84} Although obvious signs or symptoms would be expected, the complaints often appear trivial and may be ignored. Reported cases of FUO have occurred in children with mastoiditis, sinusitis, chronic or recurrent otitis media, chronic or recurrent pharyngitis, tonsillitis, peritonsillar abscess, and nonspecific upper respiratory tract infection. A parapharyngeal inflammatory pseudotumor manifested as FUO has been reported in a 3-year-old girl in whom anemia and weight loss also developed. The cause never was discerned, but the symptoms resolved after surgical removal of the inflammatory mass.²⁸

Noninfectious Causes of Fever of Unknown Origin

Central Nervous System Dysfunction

Children with severe brain damage can have dysfunctional thermoregulation, and body temperature in some of these patients can remain elevated for months. Cases of otherwise neurologically normal children who have had fever as a result of central dysfunction also have been reported. Berger¹⁸ discussed a 16-year-old child with recurrent episodes of fever that were thought to represent a form of epilepsy but disappeared when treatment with phenytoin was begun. Wolff and associates¹⁰⁹ reported a 14-year-old child with cyclic episodes of fever, nausea, vomiting, and emotional disturbance caused by a central nervous system lesion.

Diabetes Insipidus

Central and nephrogenic diabetes insipidus can cause FUO in infants and young children. Polyuria and polydipsia may not be appreciated during infancy. Hyperthermia, weight loss, and peripheral vascular collapse can ensue. Signs of dehydration or an increased serum concentration of sodium suggests the diagnosis. The diagnosis is established by simultaneous measurements of urine and serum electrolytes and osmolality during periods of normal hydration and after carefully controlled periods of water deprivation. Serum levels of antidiuretic hormone also can be measured.

Drug Fever

Nearly any medication can be associated with an allergic reaction, including fever. The offending agent may be a prescribed drug, an over-the-counter preparation, or a street drug such as amphetamine or 1-[1-phenylcyclohexyl]piperidine (phencyclidine [PCP]). Atropine, whether taken systemically or used topically in the form of eye drops, can cause elevation of temperature. Phenothiazines and anticholinergic drugs can inhibit sweating and impair regulation of temperature. Epinephrine and related compounds can affect thermoregulatory control mechanisms and produce fever. Drug fever can be low-grade or high and spiking. Fever can be continuous or intermittent. Discontinuation of the drug generally is followed by disappearance of the fever within 48 to 72 hours, but it sometimes persists for as long as a month as a result of slow excretion of the offending agent.

Factitious Fever

A parent or patient may report the presence of fever that does not exist. The reading of the thermometer can be increased by immersing the bulb in hot liquid or by rinsing the mouth with hot liquid immediately before inserting the thermometer. Clues to factitious fever include absence of tachycardia, malaise, or discomfort despite a markedly elevated temperature; apparent rapid defervescence unaccompanied by diaphoresis; failure of the temperature curve to follow the normal diurnal variation of body temperature; hyperpyrexia; and normal temperature reading when the temperature is obtained rectally by someone who remains in attendance during the procedure. The presence of fever also can be confirmed or excluded by measuring the temperature of a freshly voided urine specimen. The current use of electronic thermometers in most hospitals decreases the possibility of factitious fever in that setting because the nurse or aide usually brings in the thermometer and stays in attendance during the relatively brief period of insertion. In more unusual cases, the patient or parent can induce fever by the injection of infective or foreign materials.

Familial Dysautonomia

Familial dysautonomia (Riley-Day syndrome), an autosomal recessive disorder, is characterized by autonomic and peripheral sensory nerve dysfunction. Eighty percent of patients are children of Jewish parentage, particularly Ashkenazi Jews. Defective regulation of temperature can result in hypothermia or hyperthermia.³³

A careful history and physical examination can reveal poorly coordinated swallowing movements that lead to recurrent aspiration and pneumonia; recurrent episodes of vomiting; excessive salivation; excessive or diminished sweating; diminished formation of tears; periods of hypotension, hypertension, or both; and erythema or blanching of the skin. The fungiform papillae of the tongue are absent or diminished in number, and the sensation of taste is deficient.⁹³ Self-mutilation or

multiple sites of skin trauma can reflect diminished or absent pain sensation peripherally. Deep tendon reflexes are diminished; corneal reflexes are impaired; and mental deficiency, dysarthria, and emotional lability are common findings.

Placement of methacholine (2.5%) into the conjunctival sac produces pupillary constriction in children with familial dysautonomia but no response in normal children. Intravenous infusion of norepinephrine is followed by an exaggerated pressor response, and the hypotensive response to infusion of methacholine is increased.

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis is characterized by prolonged fever, hepatosplenomegaly, cytopenia, and hyperferritinemia and hemophagocytosis in the bone marrow, liver, spleen, or lymph nodes.^{51,78} It is a life-threatening and unusual disorder in which uncontrolled proliferation of activated lymphocytes and histiocytes results in unregulated hypersecretion of inflammatory cytokines. Hemophagocytic lymphohistiocytosis can be primarily a familial disease or can be manifested as a reactive process triggered by infection, malignancy, immunologic disease, or drugs.

The diagnosis of hemophagocytic lymphohistiocytosis is suggested by fever, hepatosplenomegaly, cytopenia in at least two cell lines, hypertriglyceridemia or hypofibrinogenemia, and an elevated ferritin level. Other laboratory abnormalities associated with hemophagocytic lymphohistiocytosis can include low or absent natural killer cell activity or elevated soluble CD25 (α chain of the interleukin-2 receptor), but these studies take time for results to return from reference laboratories.⁵⁴ Because this disorder can be manifested initially as FUO and progress to masquerade as overwhelming sepsis, a high index of suspicion is required for establishing the diagnosis. Further investigation should include evaluation of bone marrow or lymph nodes for the presence of hemophagocytosis. Therapy should include treatment of the underlying infection or trigger, if one exists, in addition to appropriate immune modulation therapies. A substantial proportion of hemophagocytic lymphohistiocytosis cases progress rapidly to death despite administration of appropriate chemotherapy.^{51,54,78}

Inflammatory Bowel Disease

Fever is a prominent feature in many children with inflammatory bowel disease.^{29,57,104} A greater percentage of children than adults with regional enteritis have fever. Appropriate contrast-enhanced radiographic studies of the intestines should be undertaken in children with prolonged FUO, even in the absence of findings specifically referable to the gastrointestinal tract, especially if the erythrocyte sedimentation rate is elevated and if the patient has anemia, weight loss, failure of linear growth, or a positive stool guaiac test.

Ulcerative colitis can be manifested as FUO, although less commonly than with regional enteritis. In patients with ulcerative colitis, symptoms referable to the gastrointestinal tract generally are present at the time that the patient is febrile.

Infantile Cortical Hyperostosis

The cause of infantile cortical hyperostosis (i.e., Caffey disease) is unknown. The decreased incidence in recent years suggests an infectious, possibly a viral, cause. Spontaneous hyperplasia of subperiosteal bone begins during infancy and is associated with swelling of the overlying tissues. The skull, mandible, clavicles, scapula, and ribs are affected most frequently, but in some children the long bones and even the metatarsal bones can be involved. Most patients have persistent fever, sometimes as high as 40°C (104°F). Tenderness over the affected regions, irritability, elevated erythrocyte sedimentation rate, and leukocytosis are common findings. The diagnosis is established by the clinical picture in conjunction with radiographically demonstrated periosteal involvement.

Juvenile Idiopathic (Rheumatoid) Arthritis

Juvenile idiopathic arthritis is a chronic inflammatory disorder that usually is manifested as one of three distinct syndromes: the systemic form, characterized by high, spiking temperatures (generally once or twice each day), evanescent rash, and lymphadenopathy; a polyarticular

form; and a monarticular or pauciarticular form. Fever is associated with all three manifestations but occurs most commonly in the systemic form, in which case it is present in nearly 100% of patients. This form also is the one most likely to be manifested as FUO.²³ Arthritis may not develop for months to years after onset of the fever. The diagnosis often needs to be made by exclusion because no laboratory findings are specific for the diagnosis.

Periodic Fevers

The periodic fever disorders, also known as unprovoked inflammatory events that sometimes can occur without accompanying fever, are rare heritable disorders characterized by recurrent (periodic or irregular) attacks of fever and inflammation.¹⁰² Between attacks, patients feel well. These disorders include familial Mediterranean fever and hyperimmunoglobulinemia D with periodic fever syndrome, which are autosomal recessive diseases. Familial Mediterranean fever is caused by a mutation in the *MEFV* gene, which encodes the protein pyrin. The illness is characterized by fever for 1 to 3 days accompanied by abdominal pain, pleurisy, and arthritis or arthralgia. Laboratory findings include peripheral leukocytosis and elevation of acute-phase reactants. The episodes occur irregularly. Persistent inflammation can lead to secondary amyloidosis. The disease occurs most commonly in Armenians, North Africans, Sephardic Jews, and Turks, and sometimes in Ashkenazi Jews, Italians, and Greeks or persons of other ethnicities.

Hyperimmunoglobulinemia D with periodic fever syndrome is associated with mutations in the *MVK* gene that encodes mevalonate kinase. Disease commonly presents before the age of 1 year, with episodes of fever lasting 3 to 7 days accompanied by cervical lymphadenopathy, abdominal pain, and vomiting or diarrhea.^{36,42} Patients also can have aphthous ulcers, rash, splenomegaly, and arthritis or arthralgias. Attacks may occur at irregular intervals and can be triggered by stress, vaccination, and viral infections. Immunoglobulin (Ig) D levels are elevated, and most patients also have elevated IgA. Secondary amyloidosis is rare.

Other periodic fever syndromes include tumor necrosis factor receptor-associated periodic syndrome; pyogenic sterile arthritis, pyoderma gangrenosum syndrome, and acne; and Blau syndrome. These are rare disorders that are autosomal dominant in transmission. The genes associated with these disorders encode proteins that share domains involved in innate immunity and apoptosis. Muckle-Wells syndrome, familial cold autoinflammatory syndrome, and neonatal-onset multisystem inflammatory disorder are cryopyrin-associated periodic syndromes, a group of overlapping autoinflammatory disorders in which fever is an accompanying but not major feature of illness.

The syndrome of periodic fever with aphthous stomatitis, pharyngitis, and adenitis is a relatively common periodic fever syndrome. Symptoms such as fever, pharyngitis, cervical lymphadenopathy, and mild aphthous ulcers usually recur at 3- to 4-week intervals, generally beginning abruptly and resolving spontaneously in 3 to 5 days. Leukocytosis and elevation of inflammatory markers occur during the acute episode and normalize in between. The cause of this syndrome remains unknown.³⁷

Toxic Shock Syndrome

Jeffrey Suen

Illnesses resembling toxic shock syndrome (TSS) have been reported since 1927,^{7,87,99,247,273} but TSS was first defined as a disease in 1978 by Dr. James K. Todd and colleagues using criteria designed for epidemiologic studies (Box 64.1).²⁶¹ TSS is characterized by fever, hypotension due to massive loss of fluid from capillaries into the interstitial space, and subsequent multisystem end-organ dysfunction. It has unique clinical manifestations not generally noted in septic shock, including diffuse erythroderma, delayed desquamation of the palms and soles, and conjunctival and pharyngeal hyperemia.

When first described, TSS was associated with menses, tampon use, and a distinctive type of *Staphylococcus aureus*. Patients with menses-associated TSS (menstrual TSS) had cervicovaginal colonization with strains of *S. aureus*¹⁹ that made a toxin initially called *staphylococcal enterotoxin F*²⁰ or *pyrogenic exotoxin C*²²⁹ but now known as TSST-1. Toxic shock–like syndromes were subsequently recognized in cases not associated with tampons (nonmenstrual TSS)²¹⁵ and in patients infected with toxin producing *Streptococcus pyogenes*.²⁸² TSST-1, staphylococcal enterotoxins, and streptococcal pyrogenic exotoxins A and B are now recognized to be “superantigens.” These superantigens are potent stimuli of T-cell proliferation, causing massive release of cytokines (interleukin-1 [IL-1], IL-2, tumor necrosis factor- α [TNF- α], and TNF- β) that mediate the systemic manifestations of the disease.^{146,240}

EPIDEMIOLOGY

Surveillance and Incidence

The first 12 cases of epidemic TSS were identified and reported to the Centers for Disease Control and Prevention (CDC) between July 1979 and January 1980.^{37,69,238} In May 1980, shortly after surveillance for TSS began,^{72,123,152,199} the CDC reported findings of the first 55 cases, 95% of which occurred in women and had onset during menstruation.³⁷ By June 1980, case-control studies statistically linking the occurrence of menstrual TSS with tampons had been completed.^{69,238,144} Superabsorbent tampons, particularly the Rely brand and those containing polyacrylate, were found to have a high association with TSS.^{21,30,36,38,226} Between 1983 and 1994, the CDC received reports of 2509 confirmed cases; 95% occurred in females, 89% had an onset of TSS associated with menstruation, and 99% occurred in tampon users.^{42,214}

Between 1980 and 1996, the incidence of menstrual TSS was highest in the ages 15 to 25 years (median age, 21 years, 1979–80; 20 years, 1981–86; 25 years, 1987–96).^{116,121,214} Roughly one-third of cases occurred in adolescents 15 to 19 years of age (Fig. 64.1).²⁷² A striking 97% of cases occurred in whites, who comprise 83% of the U.S. population.²¹⁴ Although TSS cases occurred throughout the United States, the five states of Wisconsin, Minnesota, Colorado, Utah, and California accounted for 44% of the total reported cases but represented only 16% of the U.S. population.^{214,264} In addition to differences in surveillance and menses-related practices, the distribution in age, race, and geography have been attributed to the prevalence of toxin-producing organisms and antibody to exotoxins.^{103,204,214,215,272}

Geographic differences continued even with an increase in the relative proportion of nonmenstrual cases.³⁰

The mean age of patients with nonmenstrual TSS (27 years through 1982, 30 years in 1986) is significantly higher than that for menses-associated cases.^{116,215} The number of confirmed cases reported in children younger than 10 years of age is surprisingly low, particularly in light of their low antibody titers to TSST-1 and more frequent nasal colonization with TSST-1–positive strains.^{30,136,272,281} The racial distribution is less pronounced, with 87% occurring in whites, who make up 83% of the U.S. population, and the ratio of males to females with nonmenstrual TSS is closer to that in the general population.^{214,215}

Since 1980, when the rate of menstrual TSS was as high as 12.3 per 100,000 women of menstruating age,^{69,152,199,210} the incidence has steadily declined to less than 1 case per 100,000 (Fig. 64.2).^{79,116,277} The menstrual TSS–related mortality rate has decreased from 5.5% in 1979–80 to 1.8% in 1987–96.¹²¹ The striking reduction in the incidence of menstrual TSS has been attributed to changes in composition and usage of tampons and the impact of publicity on early recognition of symptoms.^{41,69,70,72,103,198,233} Since 1982, when the U.S. Food and Drug Administration (FDA) required that information on TSS risks appear on tampon packages,^{83,187,269} tampon composition has changed to cotton and rayon combinations with the removal of additives.²²⁸ Products with high absorbency decreased from 42% to 1%,^{41,199} and tampons containing polyacrylate were withdrawn by major manufacturers.¹⁹¹

The incidence of postoperative cases of TSS after all types of surgeries has been estimated to be 3/100,000.¹²⁰ For ear, nose, and throat surgery, the incidence is higher (16.5 per 100,000).¹³⁵ Overall the average annual incidence of nonmenstrual TSS has been estimated to be 0.32 per 100,000 (95% confidence interval [CI], 0.12–0.67).⁷⁹ Largely due to the declining incidence of menstrual TSS, the relative proportion of nonmenstrual cases reported has increased from 14% during 1979–86 to 42% in 1994.^{30,42,116,122} The case-fatality ratio for nonmenstrual cases has remained between 5.3% and 8.5%.^{30,42}

Risk Factors for Toxic Shock Syndrome

The primary risk factors necessary for the development of TSS include colonization or acquisition of a toxin-producing strain of *S. aureus*, absence of protective antitoxin antibody, and an infected site with or without a foreign body. The main distinction between menstrual and nonmenstrual TSS is the nature of the infected site. While menstrual TSS involves cervicovaginal colonization or infection associated specifically with tampon use, cases of nonmenstrual TSS reported to the CDC include nonsurgical staphylococcal cutaneous and subcutaneous infections, 22%; postsurgical infections, 15%; childbirth or abortion, 15%; vaginal infections occurring at times other than during menses, 6%; vaginal contraceptive sponge use, 5%⁶⁶; diaphragm use, 6%; and no obvious focus (presumed vaginal or pharyngeal colonization), 31% (Box 64.2).^{19,30,215}

Colonization With Exotoxin-Producing *Staphylococcus Aureus*

S. aureus is present in 20% to 40% of nasal cultures.¹³⁴ In menstruating women, 26% are colonized with *S. aureus* in at least one of three body sites (nose, vagina, or anus).²⁰⁴ Vaginal carriage rates vary from 7% in nonmenstruating women to 33% in menstruating women^{204,208} and are

BOX 64.1 Clinical Case Definition of Toxic Shock Syndrome

Clinical Findings

- Fever: Temperature of $\geq 38.9^{\circ}\text{C}$ (102°F)
- Rash: Diffuse macular erythroderma
- Desquamation: 1 to 2 weeks after onset of illness, particularly on palms, soles, fingers, and toes
- Hypotension: Systolic blood pressure ≤ 90 mm Hg for adults; <5 th percentile by age for children <16 years; orthostatic drop in diastolic blood pressure of ≥ 15 mm Hg from lying to sitting; orthostatic syncope or orthostatic dizziness
- Involvement of three or more of the following organ systems:
 - Gastrointestinal: Vomiting or diarrhea at onset of illness
 - Muscular: Severe myalgia or creatinine phosphokinase level greater than twice the upper limit of normal for the laboratory
 - Mucous membrane: Vaginal, oropharyngeal, or conjunctival hyperemia
 - Renal: Blood urea nitrogen or serum creatinine greater than twice the upper limit of normal or 5 or more white blood cells per high-power field in the absence of a urinary tract infection
 - Hepatic: Total bilirubin, aspartate transaminase, or alanine transaminase greater than twice the upper limit of normal for the laboratory
 - Hematologic: Platelets $<100,000/\text{mm}^2$
 - Central nervous system: Disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent
- Negative results on the following tests, if obtained:
 - Blood, throat, or cerebrospinal fluid cultures; blood culture may be positive for *Staphylococcus aureus*
 - Serologic tests for Rocky Mountain spotted fever, leptospirosis, or measles

Case Classification

- **Probable:** A case with 5 of the 6 clinical findings above
- **Confirmed:** A case with all 6 of the clinical findings above, including desquamation, unless the patient dies before desquamation could occur

From Wharton M, Chorba TL, Vogt RL, et al. Case definitions for public health surveillance. *MMWR Recomm Rep.* 1990;39(RR-13):1–43.

higher during menses than at midcycle.^{161,195} In healthy individuals, 14% to 39% of *S. aureus* isolates produce TSST-1, and 7% to 14% produce staphylococcal enterotoxin B. TSST-1-positive *S. aureus* is present in 1% to 5% of vaginal cultures in women, 7% of nasal cultures in hospitalized patients, and 18% of nasal cultures in children. Overall up to 7% of healthy individuals at any given time are colonized at a mucosal site with TSST-1-positive *S. aureus*.^{78,202,204} TSST-1 producing isolates has been found in 28% of patients bacteremic with *S. aureus* without TSS.⁴⁶ Presumably these patients had circulating antibody to TSST-1 that prevented the development of TSS despite *S. aureus* infection.

The majority of toxin-producing *S. aureus* isolates in both menstrual and nonmenstrual TSS cases produce TSST-1.^{19,59,160} Of the strains producing TSST-1, 60.6% also produce an enterotoxin.^{59,160} A clone producing both TSST-1 and staphylococcal enterotoxin A is associated with 88% of menstrual and up to 54% of nonmenstrual TSS cases.^{44,108,184} Isolates that produce TSST-1 in conjunction with staphylococcal enterotoxin C have been associated with severe respiratory tract TSS-associated infections.⁵⁹ Staphylococcal enterotoxin B is never co-expressed with TSST-1.⁷⁵ TSST-1-negative strains that produce staphylococcal enterotoxin B account for 38% of nonmenstrual TSS isolates.^{153,227} Patients with nonmenstrual disease infected with these TSST-1-negative strains may have a higher mortality rate.¹¹⁵

FIG. 64.1 Age distribution of patients with confirmed toxic shock syndrome (TSS) reported to the Centers for Disease Control and Prevention before April 16, 1984. The age-specific prevalence of antibodies to toxic shock syndrome toxin I (TSST-1) in a normal population in Wisconsin in the years 1960, 1970, and 1980 is indicated by the solid connected line. (Data from Vergeront JM, Stolz SJ, Crass BA, et al. Prevalence of serum antibody to staphylococcal enterotoxin F among Wisconsin residents: implications for toxic shock syndrome. *J Infect Dis.* 1983;148:692–8.)

FIG. 64.2 Menstrual and nonmenstrual toxic shock syndrome cases reported to the Centers for Disease Control and Prevention by year, 1979 to 1996. (From Hajjeh RA, Reingold A, Weil A, et al. Toxic-shock syndrome in the United States: surveillance update, 1979–1996. *Emerg Infect Dis.* 1999;5:807–10.)

While toxin producing staphylococcal strains may cluster within families, living units, and hospital settings, the occurrence of TSS clusters is a rare event.^{149,183} Probable TSS cases have developed within 24 hours in a husband and wife and in two mother-daughter pairs.¹⁰⁶ Nosocomial acquisition and transmission of TSST-1-positive organisms have been described.^{9,149,183}

BOX 64.2 Risk Factors for Staphylococcal Toxic Shock Syndrome

- I. Colonization of infection with toxin-producing *Staphylococcus aureus*
- II. Absence of protective antitoxin antibody
- III. Infected site
 - A. Primary *S. aureus* infection
 - Carbuncle
 - Cellulitis
 - Dental abscess
 - Empyema
 - Endocarditis
 - Folliculitis

 - Burns (chemical, scald, etc.)
 - Dermatitis
 - Influenza
 - Pharyngitis
 - Postpartum (vaginal delivery)
 - Superficial/penetrating trauma (insect bite, needle stick)
 - Viral infection
 - Varicella
 - D. Foreign body placement
 - Augmentation mammoplasty
 - Catheters
 - Contraceptive sponge
 - Diaphragm
 - Surgical prostheses/stents/packing material/sutures
 - Tampons
 - E. No obvious focus of infection (vaginal or pharyngeal colonization)

Absence of Protective Antibody Levels

Antibody formation to exotoxins is thought to result from mucosal colonization with TSST-1–positive *S. aureus* strains.^{9,218} Adults and children with persistent nasal carriage of a TSST-1–positive strain have high levels of antibody to TSST-1.^{204,218} Antibody titers are higher in women colonized with toxigenic *S. aureus* whether the colonization is persistent or transient.^{49,205} Patients in whom TSS develops have significantly lower levels of antibody to staphylococcal exotoxins than the general population.^{19,59} Following the episode of TSS, the antibody response to TSST-1 is typically absent or delayed.^{202,253}

The prevalence of antibody to staphylococcal exotoxins has remained stable in studies from 1960 to 1999 and is correlated with age (see Fig. 64.1).^{204,272} The increased incidence of TSS in adolescent girls is related to the lower prevalence of antibody to TSST-1 in this age group.²⁷²

Antibody to TSST-1 in a study of Wisconsin residents was found to be 47% at 1 year of age, 70% at 10 years, 88% at 20 years, and 96% for ages 30 to 50 years during the years 1960 to 1983.³⁷ A study of women across North America in 1998 to 1999 found similar results, with 85% overall and 81% of subjects aged 13 to 18 years having positive antibody to TSST-1.²⁰⁴ Transplacental antibody is present in more than 90% of infants.²⁷²

For the staphylococcal enterotoxins, by 10 years of age, the proportion of individuals with antibody titers of 1 : 100 or higher is 15% for staphylococcal enterotoxin A, 65% for staphylococcal enterotoxin B, 30% for staphylococcal enterotoxin C, 5% for staphylococcal enterotoxin D, and 20% for staphylococcal enterotoxin E. By 22 years of age, the proportion increases to 55% for staphylococcal enterotoxin A, 77% for staphylococcal enterotoxin B, and 98% for staphylococcal enterotoxin C.¹⁹

Racial, sexual, and geographic differences in antibody prevalence have been noted.²⁷² Sera randomly selected from 87 control women were seronegative more frequently for antibody to TSST-1 (24%) than were those from 66 control men (9%).²²² A 2003 multicenter study of 3012 women from Ohio, New Jersey, Florida, Arizona, and Manitoba, Canada, found similar rates of *S. aureus* colonization, but subjects from Manitoba and Arizona were significantly more likely to have a positive antibody titer than were subjects from the other locations.²⁰⁴

Interruption of Skin or Mucosal Surface

Most cases of TSS occur in patients with an altered skin or mucosal surface. Trauma or surgery in areas of the body frequently colonized with *S. aureus* (nose, skin, vagina) places individuals at enhanced risk for infection and subsequent TSS. A wide variety of types of surgeries have been associated with TSS (see Box 64.2).^{2,19,35,182,192,216,239,242,268} Primary deep-tissue staphylococcal infections (e.g., osteomyelitis, pyarthrosis, pyomyositis,⁴ endocarditis,^{211,278} renal carbuncles, and bacteremia) are rarely associated with TSS. Types of skin disruptions commonly associated with TSS include burns, surgical incisions, insect bites, needle sticks, tattoos, and varicella.^{19,29,58} Infected abrasions under casts may be focal sites of TSST-1 production.²⁴⁵

Burn wounds provide a particularly rich environment for growth of *S. aureus* and the production of toxins.* In burn centers, TSS occurs predominantly in young children with small burns.⁹⁰ In one large pediatric burn center, *S. aureus* normally was not cultured from any site on admission but was acquired within a few days of admission and became the most common wound pathogen. Sixteen percent of wound isolates of *S. aureus* produced TSST-1. Only 50% of the children had antibodies to TSST-1 on admission. A toxic shock–like syndrome developed in 13% of children.⁵¹ The mortality rate associated with TSS in children with burns may be as high as 57%.¹¹¹

TSS cases following disruption of nasopharyngeal mucosa and the respiratory tract include those associated with sinusitis,^{19,100} pharyngitis,^{19,225} parapharyngeal and submandibular abscesses,²²⁵ tracheitis,^{19,64,85,114,188} pneumonia,^{19,67} rubeola,²⁵⁴ and influenza.^{40,57,156,267} TSS occurring after ear, nose, and throat surgery has been associated with the use of nasal splints and packing materials that may disrupt the ciliary blanket.^{3,19,110,178,284}

The vaginal mucosa may be damaged during placement of tampons or barrier contraceptives,^{39,96,234} postpartum,^{20,202} or after genital surgery.^{97,201,220} Heavy colonization of the vagina without any other apparent risk factor has been associated with TSS.²¹⁵ Vaginal mucosal infections may provide the right conditions for production of TSST-1, including an aerobic environment, high carbon dioxide concentration, neutral pH, high protein and low glucose concentrations, and low to normal magnesium concentration.¹⁷⁹

Presence of a Foreign Body

Tampon use was established as a clear risk factor for the development of TSS.^{30,69,116,124,144,198,226,238} Tampons create an aerobic environment in the vagina, which normally is anaerobic.²⁷⁴ Because TSST-1 production requires oxygen, the increasing concentrations of oxygen may enhance the production of toxin. Tampons may also remove vaginal substrates that normally inhibit the growth of *S. aureus*.¹⁹ Although it has been

*References 11, 51, 55, 91, 111, 113, 117, 128, 159, 163, 265, 275.

suggested that tampons may cause vaginal ulceration leading to greater bacterial growth and toxin absorption,^{61,63,276} the types of ulcerations seen are likely induced by TSST-1 because they have been found during postmortem examination in women who had never used tampons.¹⁵¹

While TSS occurs with all brands of tampons, a greater relative risk for menstrual TSS was found with brands with higher absorbency and particular compositions.^{20,30,36,104,158,197,226} In one study, production of TSST-1 varied from undetectable levels to 300 µg/mL depending on the tampon studied.¹⁹ Two studies demonstrated enhanced production of TSST-1 in vitro by the Rely tampon, which was composed of cross-linked carboxymethylcellulose and polyester foam.^{207,229} The polyacrylate rayon and surfactant Pluronic L-92 included in some tampon brands also increase the production of TSST-1 under certain conditions.^{178,229,259}

In addition to tampons, implanted foreign material, including sutures, central venous lines, metallic or polymeric implants, Teflon splints, and gauze packing, have been documented to enhance the risk for acquiring bacterial infection.^{19,121,138} These infections are characterized by limited spread beyond the tissues in immediate contact with the implants, poor response to antibiotics, and poor healing without removal of the foreign material. The infection risk varies with the type of foreign material implanted. For example, bacterial adherence is eightfold higher for braided sutures of silk, silicone-heated blue polyester, and absorbable polyglycolic acid than for monofilament nylon.¹³⁸ Two important distinctions between TSS and other *S. aureus* infections related to foreign material are the production of exotoxin and the limited inflammation around the wound.⁹⁸

Other Potential Risk Factors

Other factors that have been examined to identify individuals at increased risk for TSS include personal hygiene practices,⁷³ human leukocyte antigen type,¹⁹ neutrophil function,¹²⁶ adherence of *S. aureus* to vaginal epithelial cells,¹⁸ alteration of the cervicovaginal flora,¹⁹ and hormonal factors.

Alteration of the vaginal flora, particularly co-colonization with *S. aureus* and Enterobacteriaceae, has been postulated to enhance the risk for development of TSS.²³⁶ A prospective study found that women who were colonized with toxin-producing *S. aureus* had higher rates of colonization with *Escherichia coli* or other Enterobacteriaceae. *E. coli* isolation rates were 54% in women with TSST-1–positive isolates, 15% in women with TSST-1–negative isolates, and 11% in women with no *S. aureus*. The significance of these findings is not clear.

Hormonal control is known to be responsible for numerous cyclic changes in vaginal pH and flora. The results of early case-control studies suggested that oral contraceptives might have an effect on vaginal *S. aureus* organisms that may produce TSS-associated toxins.^{69,164,198} However, one case-control study found neither protective effect nor enhanced risk associated with oral contraceptive use.¹¹⁶

HISTOPATHOLOGY

The histopathologic findings on postmortem examination support the concept that TSS is a toxin-mediated disease.^{1,24,28,151,200,280} Striking histopathologic similarities exist between patients with TSS and those with “scarlet fever” reported in 1936.²⁸ Typically a total absence of tissue invasion by bacteria and minimal evidence of an inflammatory reaction in most organs are noted. Findings thought to be due to a direct effect of the toxin or mediators (or both) and unrelated to hypoperfusion include subepidermal ulcerations in the cervix, vagina, esophagus, and bladder; depletion of lymphocytes in lymph nodes; a subepidermal cleavage plane in the skin; and mild inflammatory changes in the kidney, liver, heart, and muscle.

Cervicovaginal ulcerations are the only characteristic lesions noted in the genital tract of patients with fatal menstrual TSS, and such ulcers have been found in a patient with menstrual TSS who had never used tampons.^{151,202} The ulcerations are superficial, with separation occurring just beneath the basal layer. Capillary vasodilation and thrombosis with inflammation of the mucosa are present, but no deep-tissue bacterial invasion is seen. The same type of ulcer also has been found in the bladder and esophagus, which suggests that these ulcerations may be caused by the toxins or mediators and not by the use of tampons.

Although the myocardium was described as normal in one post-mortem series of TSS, in another series of eight fatal cases, all patients had evidence of focal round-cell infiltration with variable degrees of congestion, edema, and hemorrhage.^{151,200} Myxoid degeneration was found in all heart valves from four patients in one series. Sections of skeletal muscle have demonstrated only congestion, edema, focal hemorrhage or fiber necrosis, and a mild acute inflammatory infiltrate.

Varying degrees of periportal lymphocytic inflammation have been the most consistent findings in the liver; centrilobular congestion with necrosis and mild cellular degeneration also has been described.¹³³ In the kidney, toxin-mediated mononuclear interstitial nephritis may result from perivascularitis of the adventitia of the renal venules, lesions that probably precede the development of hypotension-induced acute tubular necrosis. The most characteristic findings in the spleen and lymph nodes have been lymphocyte depletion; inactive hypocellular, hypoplastic lymphoid follicles with edema; marked histiocytosis in the interfollicular areas; and hemophagocytosis.

Perivascular lymphocytic infiltrates and bullae that separate at the basement membrane are characteristic of the early skin changes in TSS.^{8,10,126} No evidence of vasculitis has been reported.

CLINICAL SPECTRUM

Acute Phase

The manifestations in TSS are the result of release of endogenous mediators after monocyte and T-cell activation by TSST-1 or the staphylococcal enterotoxins.* The physiologic changes are striking in their rapidity of onset and progression and the involvement of almost all body tissues and organs. Endothelial damage with loss of fluid from capillaries into the interstitial space results in loss of peripheral vascular resistance, loss of intravascular volume, and interstitial edema. Prolonged hypotension, interstitial edema, and vascular congestion in turn results in ischemic organ damage. The onset of illness in patients with severe disease is abrupt, with signs and symptoms including fever, chills, malaise, headache, sore throat, myalgia, muscle tenderness, fatigue, vomiting, diarrhea, abdominal pain, and orthostatic dizziness or syncope (Figs. 64.3 and 64.4).

During the first 24 to 48 hours, diffuse erythroderma, severe vomiting and watery diarrhea (often with incontinence), decreased urine output, cyanosis, and edema of the extremities may be noted. Some patients may have purpura fulminans.¹⁴⁸ Cerebral ischemia and edema result in somnolence, confusion, irritability, agitation, and occasionally hallucinations, even in individuals without hypotension. Patients with TSS have had signs and symptoms of encephalopathy, cerebral infarction, meningismus,^{14,23,122,155,243} and the cauda equina syndrome.⁸

On initial physical examination, fever, tachycardia, tachypnea, hypotension, erythroderma (generally not seen in patients with severe hypotension or in those without T cells)¹⁴² (see Fig. 64.4A), and muscle tenderness are noted in conjunction with peripheral cyanosis and edema, conjunctival hyperemia, subconjunctival hemorrhages (see Fig. 64.4B), beefy red edematous mucous membranes, somnolence, disorientation, and agitation. In menstrual TSS, edema and erythema of the inner aspect of the thighs and the perineum may be noted despite normal findings on uterine and adnexal examination.

In nonmenstrual cases, another focus of infection is present. Surgical wounds and some abscesses colonized or infected with *S. aureus* and responsible for nonmenstrual TSS often have minimal or no signs of inflammation.^{6,16,86,120,213,215,223} The production of TNF-α by macrophages in response to TSST-1 inhibits neutrophil mobilization in vitro,⁹⁸ which may provide an explanation for the absence of signs of inflammation. The incubation period for postoperative or postpartum TSS is usually 2 to 4 days but may be as short as 12 hours.¹⁶ Relatively few cases have been associated with deep-tissue infection.¹⁹ Nosocomial acquisition of TSST-1–positive organisms rarely has been documented for postoperative cases.^{9,142,176} After orthopedic procedures or in association with bone and joint infections, the clinical manifestation of TSS may be confusing as a result of the intense and generalized myalgias associated with TSS, which may be misinterpreted as postoperative musculoskeletal symptoms. The wounds usually appear to be benign.^{19,177,209,258}

(A) Diffuse erythroderma in a 7-year-old child with nonmenstrual TSS associated with osteomyelitis of the fibula. (B) Bulbar conjunctival infection and subconjunctival hemorrhage in a 24-year-old woman with nonmenstrual TSS. (B, From Bach MC. Dermatologic signs in toxic shock syndrome: clues to diagnosis. *J Am Acad Dermatol*. 1983;8:343–7.)

Laboratory Findings

Laboratory tests reflect the endogenous cytokine release, shock, and organ failure associated with TSS. Leukocytosis may not be present, but the proportion of neutrophils generally exceeds 90%. The proportion of immature neutrophils usually is 25% to 50% of the total number of neutrophils and is associated with absolute lymphopenia. Thrombocytopenia and anemia are present during the first few days and frequently are accompanied by prolonged prothrombin and partial thromboplastin times. Disseminated intravascular coagulation may be present. Sterile pyuria and cerebrospinal fluid pleocytosis are indicative of generalized involvement of the mucous membranes and serosal surfaces. Elevated blood urea nitrogen and creatinine levels reflect kidney damage,⁴⁵ and

abnormalities in liver function tests reflect liver damage and acute cholestasis.^{119,133} Hypoproteinemia and hypoalbuminemia reflect capillary leak, and profound hypocalcemia may reflect both hypoproteinemia and high serum levels of calcitonin.^{48,246} Muscle involvement is noted by an elevated creatine phosphokinase level, and the hypophosphatemia that occurs despite impaired renal function is unexplained.^{13,48} Most of these test results return to normal within 7 to 10 days of disease onset.

S. aureus is cultured from the cervix or vagina in more than 85% of patients with menstrual TSS and from the focus of infection in patients with nonmenstrual TSS. Positive blood culture results are rare findings.⁶² Antibody to TSST-1 or to the staphylococcal enterotoxins is absent at the onset of disease in more than 85% of patients.^{20,25,59,222,241,279}

BOX 64.3 Therapeutic Principles for Management of Toxic Shock Syndrome

1. Identify the focus of infection: debride and irrigate extensively and remove any foreign material
2. Isolate the organism for antimicrobial susceptibility studies
3. Administer parenteral antimicrobial therapy to stop toxin production and eradicate the organism
4. Manage systemic multiorgan actions of toxins or mediators
5. Administer fluid therapy to maintain adequate venous return and cardiac filling pressure and to prevent end-organ damage
6. Consider intravenous immunoglobulin for the following:
 - Disease refractory to initial fluid replacement and vasopressor support
 - A focus of infection that cannot be drained

Diagnosis

TSS is diagnosed clinically according to its case definition (see Box 64.1).^{71,277} Aggressive attempts to find the focus of *S. aureus* include culture of the cervix and vagina in patients with menses-associated illness and culture of other potentially infected sites in patients with nonmenstrual illness. *S. aureus* isolates can be examined for their ability to produce TSST-1, although such testing seldom is indicated. This test is of limited usefulness for nonmenstrual cases because TSST-1 is produced by only 40% to 60% of *S. aureus* isolates from such patients.¹¹⁵ Isolates from these patients can be examined for the presence of the other enterotoxins. Acute and convalescent sera can be tested for the presence of antibodies to TSST-1 and the other enterotoxins.¹³⁰ Elevated levels of anti-TSST-1 in the acute-phase serum of a patient with menstrual-associated TSS is highly unusual.

In most instances, toxin detection tests are of value only for research or for patients with chronic recurrent or atypical disease. Genes for TSST-1 and the enterotoxins have been detected in *S. aureus* strains by polymerase chain reaction^{17,140,154,167,189,232} and hybridization techniques.^{139,186,196} A noncompetitive enzyme-linked immunosorbent assay allows quantitation of TSST-1 in clinical samples.^{169,180} Reversed passive latex agglutination has been used to detect TSST-1 and enterotoxins.^{75,95} Research laboratories also have developed techniques for detecting the selective expansion of V β 2-positive T cells as evidence of host response to superantigenic toxins.^{52,162}

Treatment

The four general principles of treatment of TSS (Box 64.3) are (1) identification and drainage of the focus of toxin production, (2) identification and susceptibility testing of the organism, (3) administration of antimicrobial therapy to block synthesis of the toxin and eradicate the organism, and (4) management of the systemic multiorgan actions of the toxins or mediators.*

Location and drainage of the infected site. The focus of infection should be identified rapidly, any foreign bodies should be removed, and the site should be drained or irrigated completely even if it does not appear to be inflamed. Performing this procedure is of utmost importance because perpetuation of even a small undrained focus of infection may result in serious clinical consequences. If TSS occurs in the immediate postoperative period, the wound should be assumed to be the source of infection regardless of its benign appearance.

Identification and susceptibility testing of the organism. Isolating the organism for susceptibility testing is of critical importance. The incidence of community-acquired methicillin-resistant *S. aureus* (MRSA) infections has increased dramatically during the past 10 years.¹¹⁸ These MRSA strains may be acquired in the community by well individuals with no risk factors and are generally not multiresistant. MRSA strains are fully capable of producing TSST-1.^{82,231} TSS may be caused by either community-acquired or multiresistant hospital-acquired strains of MRSA.⁸⁸ To date, vancomycin-resistant strains of *S. aureus* are rare findings.^{43,129}

Administration of antimicrobial agents. Administration of antistaphylococcal antibiotics is indicated to stop toxin production and eradicate the organism.^{69,71} The infection may be a superficial or deep-tissue infection and may be associated with bacteremia or bacteriuria. Antistaphylococcal antimicrobial agents should be administered intravenously as soon as possible. Once the patient is stable, high doses of an oral antimicrobial agent to which the organism is susceptible can be given to complete a total course of 10 to 14 days.

Subinhibitory concentrations of the protein synthesis inhibitors clindamycin, erythromycin, clarithromycin, kanamycin, gentamicin, tetracycline, and linezolid have been shown to suppress TSST-1 production in vitro.^{81,206,230,251} In one study, clindamycin concentrations $\frac{1}{64}$ the minimal inhibitory concentration (MIC) were effective in totally blocking TSST-1 production.²⁰⁶

Data suggest that subinhibitory concentrations of β -lactam antibiotics actually may increase TSST-1 production by *S. aureus*. At a concentration of half the MIC, nafcillin can increase toxin production 10-fold more than under control conditions.⁵ The effect is not seen with vancomycin, another cell wall-active drug, thus suggesting specificity beyond merely a cell wall effect. Coadministration of a protein synthesis inhibitor with a β -lactam antibiotic blocks the effect.⁵

The choice of initial empiric antimicrobial therapy has become more complex as a result of an increase in the number of community-acquired MRSA infections and the spread of multiresistant MRSA strains in hospitals.¹⁴³ In the past, the most effective initial empiric therapy was a combination of a β -lactamase-resistant penicillin and clindamycin. With recent concern for MRSA strains causing TSS, many experts recommend initiating therapy with vancomycin and clindamycin. As an alternative for MRSA coverage, linezolid has been used successfully for treatment of staphylococcal TSS.²⁵¹ Once the results of susceptibility testing of the organism are available, therapy can be adjusted appropriately.

Management of systemic multiorgan actions of the toxins or mediators

Fluid replacement. The most important aspect of the nonspecific treatment of symptomatic patients is fluid replacement.²⁶⁰ Intravascular volume and cardiac filling pressure must be restored rapidly to achieve adequate tissue perfusion. Because of the ongoing capillary leakage, this fluid replacement may far exceed the estimated fluid requirements based on calculated maintenance and fluid deficit volumes. Some adults have required vasopressors and as much as 12 L of fluid during the first 24 hours to stabilize the circulating blood pressure. Pleural, pericardial, and peritoneal effusions and interstitial edema inevitably occur as a result of the continued vascular capillary fluid leak. Close monitoring in an intensive care unit will facilitate treatment of intravascular fluid loss, myocardial dysfunction, hemodynamic derangements, pulmonary edema, acute respiratory distress syndrome, acute renal failure, encephalopathy, and disseminated intravascular coagulation.

Intravenous immunoglobulin and toxin inhibition. High levels of antibody to TSST-1 and the staphylococcal enterotoxins are present in intravenous immunoglobulin (IVIG) preparations.^{46,51,169,202,257} These antibodies may inhibit the binding of toxins to MHC class II antigen-processing cells or interfere with presentation of toxin by these cells to the T-cell receptor.^{1,217} In animal models of TSS, both monoclonal antibodies to TSST-1 and human IVIG given at the time of inoculation of TSST-1-positive *S. aureus* prevent the development of TSS.^{26,203,235} Even when IVIG was administered 29 hours after administration of TSST-1, the increase in survival rates in the IVIG-treated animals still was significant. No adverse reactions were noted in the treated animals, and no evidence was found of disease mediated by the formation of antigen-antibody complexes.^{169–173}

Anecdotal case reports in humans have indicated a beneficial effect in treating staphylococcal TSS.^{15,51,56,173,190,202} Because IVIG is expensive and most patients respond rapidly once standard therapeutic measures are initiated, some experts reserve IVIG for patients with an inaccessible focus of infection or for those who continue to deteriorate after receiving fluid and vasopressor support (see Box 64.3). The dose most often used has been 400 mg/kg given as a single dose over the course of several hours. This dose results in a serum antibody titer of greater than 1:100, much higher than that appearing to provide immunity to TSST-1.²⁰² Some studies have used IVIG doses of up to 2 g/kg.⁶⁵ Because early

*References 47, 53, 69, 71, 105, 104, 125, 165, 226, 248, 266.

administration of IVIG possibly could blunt the immune response to TSST-1 or other toxins and increase the possibility of a recurrent episode, the potential risks and benefits of this form of therapy must be considered for each patient.

The role of endotoxin in the pathogenesis of TSS is unclear. The failure of polymyxin B and anti-J5 antiserum to alter the course of TSST-1–positive TSS in a rabbit model suggests that endotoxin may not be an important mediator of TSS.¹⁷¹ Early and sporadic case reports of TSS suggested therapeutic benefit with naloxone,⁵⁴ calcium,²⁰² and exchange transfusion in severely ill patients unresponsive to the usual forms of therapy.

Corticosteroids. Short courses of methylprednisolone or dexamethasone, if given early in the course of the disease, have been associated with a reduction in the duration of fever and the severity of illness but no reduction in mortality rates.²⁶³ In vitro, dexamethasone has been shown to downregulate TSST-1–induced cytokine production.¹⁴⁷ Because no controlled prospective study has demonstrated efficacy, the use of steroids probably should be restricted to hypotensive patients unresponsive to fluid resuscitation, antimicrobial agents, and IVIG.

Subacute Phase

Once appropriate treatment is initiated, response is usually rapid with defervescence within 48 hours. The hemodynamic changes initially observed include tachycardia, decreased systemic vascular resistance, decreased central venous pressure, hypovolemia, normal pulmonary artery wedge pressure, and an increased cardiac index.^{12,33,60,105,107} Once aggressive fluid therapy has been initiated, myocardial edema and potential failure, along with pulmonary and cerebral edema in the face of renal failure, become the most critical management issues.

The reasons for myocardial failure are unclear but probably are related to perivascular inflammation of the coronary vessels, edema, and postulated myocardial depressant factors.^{151,200} TSST-1 has been shown to inhibit systolic function in isolated rabbit atria, although at higher than usual circulating concentrations.¹⁹⁴ Arrhythmias may result from myocardial damage or electrolyte abnormalities.^{166,219}

During the decompensated stage of myocardial dysfunction, the cardiac index falls and pulmonary wedge pressure increases, with both left atrial and ventricular and diastolic diameters being at the upper limits of normal.¹⁰⁵ Reversible electrocardiographic findings include sinus tachycardia, diffuse loss of voltage, flattened T waves, and diffuse nonspecific ST-T-wave changes. If fatal arrhythmia does not occur during the decompensated stage, the toxic cardiomyopathy is reversible and rarely results in permanent changes. This process is similar to “stunned myocardium,” a transient, postischemic myocardial dysfunctional state.⁶⁰

Pulmonary edema and acute respiratory distress syndrome occur commonly in patients when massive fluid replacement is necessary and capillary leakage continues in the lungs. Pulmonary edema appears rapidly once fluid replacement is initiated and often necessitates intubation and ventilator management for several days.²⁶⁰

Forms of TSS-associated acute renal failure include prerenal azotemia and both nonoliguric and oliguric renal failure.⁴⁵ The type of renal failure manifested may depend on the degree of intravascular volume depletion. Unless severe acute tubular necrosis necessitates temporary hemodialysis, repletion of intravascular volume usually results in rapid restoration of renal function and, ultimately, diuresis. Permanent renal damage is an extremely rare event.⁵³

Management of fluids, electrolytes, and metabolic acidosis in patients with TSS is complex. Although tetany is a rare occurrence, severe hypocalcemia may be life-threatening and should be corrected.^{48,202,246} Most patients require potassium replacement and management of metabolic acidosis. The use of colloid for fluid replacement and removal of the toxin stimulus for capillary leakage ultimately correct the hypoproteinemia.

The typical dermatologic manifestations follow a predictable sequence (see Fig. 64.3). A flaky desquamation begins on the trunk and extremities 5 to 7 days after the onset of symptoms. From days 10 to 12 and for as long as a month, the characteristic full-thickness desquamation of the fingers, toes, palms, and soles takes place (Fig. 64.5). A variety of atypical dermatologic manifestations, including petechiae and subepidermal bullae, have been described.^{10,93,131} Many patients exhibit desquamation

FIG. 64.5 Universal full-thickness desquamation of the (A) hands and (B) feet first noted 7 to 14 days after disease onset and persisting for up to 30 days.

of the mucous membranes, which is particularly painful when the oral mucous membranes are involved.⁴⁷ In addition, a small number of patients will have reactivated herpes simplex virus type 1 or 2 lesions with the acute illness.⁴⁷ A late-onset pruritic maculopapular rash with edema and low-grade fever unrelated to antimicrobial therapy occurs in more than 50% of menses-associated cases within 7 to 14 days of disease onset.^{47,76} The cause of this late-onset rash is unknown.

The hematologic system seldom is involved with major complications in TSS. Although disseminated intravascular coagulation may be present, gastrointestinal, uterine, or cerebral bleeding rarely occurs. While thrombocytopenia may be present initially in patients with disseminated intravascular coagulation, thrombocytosis is typical in the recovery phase. Mild to moderate normocytic, normochromic anemia, likely due to a combination of hemodilution and suppressed red blood cell synthesis, develops in almost all patients with TSS and resolves during convalescence.^{50,47} Hypoferrinemia occurs commonly.⁵⁰

The relatively common toxic or ischemic encephalopathy, rarely complicated by seizures, resolves slowly during the first 4 to 5 days of hospitalization. The gastrointestinal, musculoskeletal, and hepatic changes resolve rapidly. Sequelae associated with these changes are rare, except for prolonged muscle weakness.^{46,74} Joint manifestations generally are self-limited.^{19,109}

Outcome and Sequelae

Death associated with TSS usually takes place within the first few days of illness, but it may occur as late as 15 days after presentation. Fatalities have been attributed to refractory cardiac arrhythmias, cardiomyopathy,

irreversible respiratory failure, and, rarely, bleeding caused by coagulation defects.^{151,200} The duration of circulation of toxins and mediators and the associated hypotension may be the best predictors of the severity of the end-organ damage.

Sequelae that appear to be related to a prolonged period of hypotension include chronic renal failure, gangrene, and telogen effluvium.^{74,141,175,221,224} Hair and nail loss occurs 4 to 16 weeks after onset of the illness, with restoration taking place in 5 to 6 months.^{19,22,47}

Other sequelae, such as neuropsychological abnormalities, prolonged myalgia and weakness, carpal tunnel syndrome, chronic dermatitis, Raynaud syndrome, and new allergies are explained less easily.⁴⁶ Impaired memory and concentration have been found in patients who did not require any therapy other than intravenous fluids to restore their blood pressure.^{162,221} Fertility patterns and pregnancy outcomes were similar in controls and women with TSS, both before and after the illness.⁷⁴

Recurrences

Recurrences for both menstrual and nonmenstrual TSS are well described, usually associated with inadequately treated disease.^{6,47,69,71,164,202,253} A small number of patients with menstrual disease and repeated tampon exposure have experienced as many as 6 to 12 recurrences. In most patients the first episode is the most severe.⁷¹ Antistaphylococcal antimicrobial therapy for 10 to 14 days and discontinuation of tampon use reduces the rate of recurrence significantly.⁷¹

The absent or delayed antibody response to TSST-1 found in both menstrual and nonmenstrual TSS patients probably accounts for the continued susceptibility to TSS and high recurrence rate.^{19,25,157,222,241,253,279} The fact that superantigenic toxins are not processed by antigen-processing cells and T lymphocytes as conventional antigens may provide an explanation for the poor convalescent antibody response to these antigens.¹⁴⁶ In mice and one patient with TSS, in vivo TSST-1–induced proliferation was followed by hyporesponsiveness of TSST-1–responsive $V_{\beta}2^{+}$ T cells.¹⁵⁷

Culture-negative, menses-associated recurrent episodes of TSS continue to be found in a small number of patients despite discontinuation of tampon use and administration of appropriate antimicrobial therapy during the acute episode.⁷¹ Administration of an oral β -lactamase-resistant antistaphylococcal antimicrobial agent during menses has been tried in an attempt to prevent these recurrences but is not always successful. In recurrent cases resistant to this form of prophylaxis, consideration could be given to the empiric use of rifampin, clindamycin, erythromycin, or an oral contraceptive.¹⁶⁴

Atypical Manifestations

Mild Disease

Recognition of mild episodes of menstrual TSS is particularly important because of the risk of recurrence without appropriate therapy.^{49,69,71,78,165,165} Patients with mild TSS typically do not form antibody to TSST-1 during convalescence.^{19,25,222,241,279} A mild episode may be recognized only in retrospect, after desquamation, a recurrent episode, or both develop.²⁰²

The presence of any combination of fever, headache, sore throat, diarrhea, vomiting, orthostatic dizziness, syncope, and myalgia in a menstruating woman or an individual with a potential *S. aureus* infection should raise suspicion of TSS. A positive culture for *S. aureus* is helpful but not diagnostic because *S. aureus* may be cultured from the cervix or vagina in up to 33% of menstruating women.^{161,208} Other laboratory data usually do not reflect multisystem involvement in mild disease, and assays for TSST-1 in body fluids are investigational.^{168,271} Support for the diagnosis of mild TSS depends on the constellation of findings present, including subsequent desquamation of the palms, soles, toes, or fingers; demonstration that *S. aureus* isolates from the site of infection produce TSST-1 or an enterotoxin; absence of antibody to TSST-1 or enterotoxins in acute-phase serum; and recurrent disease.

Recalcitrant Erythematous Desquamating Disorder

An atypical, subacute variant of TSS has been described in patients with acquired immunodeficiency syndrome (AIDS) and labeled recalcitrant erythematous desquamating disorder. *S. aureus* strains producing TSST-1 or staphylococcal enterotoxins A or B have been isolated from patients with AIDS presenting with diffuse erythema, extensive cutaneous

desquamation, hypotension, and variable multiorgan involvement.^{56,84,145} The illness is recalcitrant, prolonged, and characterized by multiple recurrences. In one patient, elevated levels of TNF and IL-6 were found during severe episodes. When antitoxin antibodies have been measured during recurrence, they have been undetectable. Two patients responded well to IVIG.^{56,145} TSST-1 and the enterotoxins may exacerbate human immunodeficiency virus type 1 (HIV-1) infection because these toxins have been shown to activate HIV-1 gene expression in vitro.¹¹² Patients with the combined cellular and humoral immunodeficiencies of AIDS may be at particular risk for the development of severe, frequent, and prolonged episodes of TSS.^{56,84,102,145,244}

Neonatal Toxic Shock Syndrome–like Exanthematous Disease

A toxic shock–like illness related to TSST-1–producing MRSA, labeled neonatal toxic shock syndrome–like exanthematous disease (NTED), was initially described in neonates in Japan²⁵⁶ and subsequently recognized in France.²⁷⁰ These infants present in the first week of life with a combination of a generalized erythematous macular rash, thrombocytopenia, elevated acute-phase reactants, and fever. Patients are colonized with a single clonal type of MRSA that produces TSST-1 and staphylococcal enterotoxin C.¹⁴⁴ Although no focus of infection is present and no exotoxins are detectable in serum, analysis of T cells shows the selective expansion of $V_{\beta}2$ -positive T cells typically found in response to TSST-1.^{255,256} Maternal IgG antibody to TSST-1 plays a protective role in preventing NTED.²⁵⁵ Although complications occur in premature neonates, term infants typically recover within 5 days without active treatment. The limited disease has been attributed to the minute amount of exotoxin from colonized sites and the high susceptibility to induction of anergy in the immature T cells of neonates.^{255,256}

Streptococcal Toxic Shock Syndrome

An increase in the incidence and severity of *S. pyogenes* was recognized in the 1980s. These infections included septicemia, necrotizing fasciitis, and a toxic shock–like syndrome. In 1993, the Working Group on Severe Streptococcal Infections proposed a consensus definition for streptococcal TSS based on clinical criteria including isolation of group A streptococci from a normally sterile site, hypotension, and two or more of the following: renal impairment, coagulopathy, liver dysfunction, acute respiratory distress syndrome, erythematous macular rash, and soft tissue necrosis.²⁸²

Since the 1990s, the rate of severe streptococcal infections has approximated 2 to 4 cases/100,000 per year. In adults, streptococcal TSS comprises 10% to 15% of severe streptococcal infections, with a mortality rate of 30% to 70%.^{68,77,150} Streptococcal TSS is less common in children and carries a lower mortality rate than in adults. A multicenter study covering a US population of 29.7 million from 2000 to 2004 identified 5400 cases of invasive group A streptococcal infection (3.5 per 100,000 per year), including 572 children younger than 10 years of age. Of the 572 children with severe streptococcal infection, 26 (4.6%) developed streptococcal TSS with a 7.2% case-fatality rate.¹⁹³

Streptococcal TSS is similar to staphylococcal TSS in that it is mediated by superantigenic toxins and results in endothelial damage, hypotension, and multisystem organ involvement. Both cell-associated and soluble streptococcal virulence factors, including M protein and pyrogenic exotoxins A and B, have been implicated as superantigens mediating the systemic effects of streptococcal TSS.^{31,94,127} It differs from staphylococcal TSS in numerous respects, including severe generalized hyperesthesia; extreme pain at the site of skin involvement; a slower onset over the course of several days; typical absence of vomiting, diarrhea, and conjunctival injection; and the frequent absence of erythroderma or the presence of only a sandpaper-like rash.^{56,248,250} In a multinational European study conducted from 2003–04, streptococcal TSS was most often associated with skin and soft tissue infections, particularly cellulitis and necrotizing fasciitis, followed by septic arthritis, bacteremia, sepsis, and meningitis. Notably, 50% of the cases of necrotizing fasciitis were complicated by streptococcal TSS.¹⁵⁰

Treatment follows the same principles as for staphylococcal TSS: identification of the focus of toxin production, identification and susceptibility testing of the organism, administration of antibiotic therapy to kill the organism and block synthesis of the toxin, and management

of the systemic multiorgan actions of the toxins. Although penicillin is the drug of choice for treatment of most group A streptococcal infections, initial broad gram-positive coverage with vancomycin and clindamycin has been advocated given the clinical overlap between streptococcal and staphylococcal TSS. The addition of clindamycin to inhibit protein synthesis is beneficial in cases of streptococcal as well as staphylococcal TSS.²⁴⁸ In a mouse model of myositis caused by *S. pyogenes*, clindamycin was more efficacious than penicillin.^{89,249,252}

IVIG as adjunctive therapy for streptococcal TSS has been supported by in vitro studies²¹⁸ and case reports in humans,^{15,32,185,283} but clinical studies have been inconclusive.²³⁷ Downregulation of the lymphokine production induced by streptococcal pyrogenic exotoxin A by IVIG has been demonstrated in vitro.^{185,241} A multicenter, randomized, double-blind, placebo-controlled trial to study IVIG for streptococcal TSS in adults showed 3.6-fold higher mortality in the placebo group. However, statistical significance was not achieved because the study identified only 10 IVIG recipients and 11 placebo patients before premature termination due to slow patient recruitment.⁶⁵ As with staphylococcal TSS, IVIG has been advocated for cases of streptococcal TSS that are refractory to aggressive therapy or for patients with an inaccessible focus of infection.

Several patients with TSS have been reported to be simultaneously infected with *S. aureus* and *S. pyogenes*.⁹² Determining which infection primarily was responsible for the manifestations or whether an amplified effect of exotoxins from both organisms was present was not possible.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of TSS includes clinical entities in which a rapid onset of fever, erythroderma-like rash, hypotension, and multisystem involvement are observed (Table 64.1).^{34,101,174,181,189,202,212}

PREVENTION AND PROPHYLAXIS

To decrease the risk for development of menstrual TSS, in 1982, the Institute of Medicine Committee on TSS recommended that women, particularly adolescents, minimize their use of high-absorbency tampons.¹³² The committee also recommended that women who have had TSS not use tampons. Although the frequency of changing tampons has not been associated with risk for TSS, limiting individual tampon use to less than 12 hours might decrease the risk for menstrual TSS. Women using intravaginal contraceptive devices also should be informed of the potential increase in risk for development of TSS.²³⁴

For prevention of nonmenstrual TSS, surgical antimicrobial prophylaxis has had limited efficacy. Perioperative systemic antistaphylococcal antibiotics did not prevent TSS in four patients^{27,223} and did not eradicate nasal carriage of *S. aureus*.¹³⁷ Topical bacitracin ointment on nasal packing

did not prevent the development of TSS.^{27,80,135,137} Most authors contend that the rare risk for development of postoperative TSS is comparable to the risk for having a severe antimicrobial reaction and that perioperative antimicrobial prophylaxis is not indicated for clean procedures of short duration.^{120,213} Effort should be intensified to recognize postoperative cases early; to open, explore extensively, and irrigate wounds; and to provide immediate antimicrobial and supportive therapy for suspected TSS. In burn patients, issues regarding the use of prophylactic antibiotics and occlusive dressings are unsettled.⁹¹

Pediatric Acute Respiratory Distress Syndrome

Jessica E. Ericson • Ira M. Cheifetz

Acute respiratory distress syndrome (ARDS) represents the final common pathway and clinical presentation of the most severe acute lung injury (ALI), which may be precipitated by various pulmonary (direct) or nonpulmonary (indirect) insults. Infections are an important cause of ARDS in children, with pneumonia and sepsis being most common.^{41,118} ARDS is an important consideration in the setting of pediatric infectious diseases, given the wide range of infections that may lead to this

complication and its associated morbidity and mortality.^{41,118} Morbidity, mortality, and resource usage related to ARDS also increase during outbreaks of infectious diseases, as seen during the 2009–10 H1N1 influenza pandemic.^{36,90} This chapter will discuss the definition, pathophysiology, presentation, and clinical management of children with ARDS, with an emphasis on aspects that may be of particular interest to pediatric infectious diseases specialists.

DEFINITION

Although first described by Ashbaugh and colleagues in 1967,⁸ a formal definition of ARDS was not developed until 1994 when the American-European Consensus Conference (AECC) defined ARDS as follows¹³:

1. Acute onset of respiratory symptoms
2. Frontal chest radiograph with bilateral infiltrates
3. Partial pressure of oxygen (PaO_2) to fraction of inspired oxygen (FiO_2) ratio (P/F ratio) 200 mm Hg or less
4. No clinical evidence of left atrial hypertension as defined by a pulmonary capillary wedge pressure less than 18 mm Hg (if measured)

The AECC also designated the term acute lung injury (ALI) as a part of the spectrum of ARDS, and ALI is defined by a P/F ratio between 201 and 300 mm Hg. This formal definition allowed for significant research and clinical advances to occur but had important limitations related to interrater reliability of the chest radiograph interpretation and the inability of the P/F ratio to fully explain the respiratory status of the patient.

A subsequent definition that addressed these limitations is commonly referred to as the Berlin Definition of ARDS and was developed in 2011 by the European Society of Intensive Care Medicine in collaboration with the American Thoracic Society.^{69,91} The term ALI was removed in favor of considering ARDS to be a single entity with three subgroups based on the severity of hypoxemia (i.e., mild, moderate, and severe). The Berlin Definition of ARDS takes into account the timing of onset, the degree of respiratory support (positive airway pressure), and the overall fluid status. This new definition also allowed for the use of either computed tomography (CT) of the chest or standard chest radiograph as part of the diagnostic criteria for ARDS.

The Berlin definition, however, failed to consider differences between adults and children in the presentation and management of ARDS. In 2015, after a 2-year process, the Pediatric Acute Lung Injury Consensus Conference (PALICC) published pediatric-specific definitions for ARDS and recommendations regarding management and suggested priorities for future research. PALICC defined pediatric ARDS (PARDS) with the use of the oxygenation index ($[\text{FiO}_2 \times \text{mean airway pressure} \times 100] / \text{PaO}_2$) or the oxygen saturation index ($[\text{FiO}_2 \times \text{mean airway pressure} \times 100] / \text{SpO}_2$) as a means of assessing severity (Table 65.1).⁵⁵ Some of the key PALICC recommendations were (1) no age criteria for the definition of PARDS in order that the pathophysiology of PARDS be better studied across the spectrum of age groups in future studies; (2) exclusion of perinatal-related lung injury; (3) inclusion of infants and children requiring noninvasive ventilation, as well as (4) inclusion of those with

congenital heart disease and chronic lung disease; and (5) inclusion of patients with unilateral lung disease.

PATHOLOGY AND PATHOPHYSIOLOGY

The clinical stages of ARDS coincide with three pathologic stages: exudative stage, proliferative stage, and fibrotic stage. The exudative stage is characterized by accumulation of protein-rich edema fluid in the alveoli following direct or indirect injury to the alveolar-capillary membrane (see Table 65.1). Neutrophils play a predominant role in this stage of ARDS. Pulmonary compliance is worsened by the presence of edema, widespread atelectasis, and the inactivation of surfactant that results from the presence of fibrin and other plasma proteins and inflammatory mediators in the alveolar space.^{64,97} Microthrombi develop within the pulmonary vasculature and numerous vasoactive mediators are released from inflammatory cells and the activated endothelium contributing to the development of elevated pulmonary vascular resistance and the ventilation/perfusion abnormalities characteristic of ARDS. The degree of epithelial injury and the subsequent ability to clear edema fluid, along with the reversibility of pulmonary hypertension, are important predictors of outcome in ARDS.^{67,111}

The proliferative stage occurs 1 to 3 weeks after the initiation of injury and is characterized by attempted repair of the disrupted alveolar-capillary membrane. The mechanism of this repair requires not only the close coordination of numerous growth factors but also an intact basement membrane to provide a platform for cell adhesion and migration.⁸² The ability of the alveolar epithelium to remove edema fluid depends on the degree of inflammation and injury in the exudative stage. Antiinflammatory cytokines such as interleukin-10 (IL-10) and lipid mediators are particularly important mechanisms aimed at limiting the degree of injury.⁶⁸ If lung injury and inflammation persist, the patient may develop severe physiologic abnormalities and may progress to the fibrotic stage of ARDS.

The fibrotic stage may be seen as early as 5 to 7 days after the onset of disease, although this degree of injury may not be clear for several weeks. Histologically the alveolar space becomes filled with mesenchymal cells, and lung tissue is replaced by collagenous tissue.⁵⁷ In addition, vascular changes in the fibrotic stage can lead to increased thickness of the pulmonary vasculature and even obliteration of small capillaries. Overall these changes markedly decrease the available surface area for gas exchange and result in decreased exercise tolerance in survivors of ARDS. In some patients, intractable respiratory failure or chronic lung disease result, necessitating prolonged ventilator support.

TABLE 65.1 Pediatric Acute Respiratory Distress Syndrome Definition From the Pediatric Acute Lung Injury Consensus Conference (2015)

Age	Exclude patients with perinatal related lung disease				
Timing	Within 7 days of known clinical insult				
Origin of Edema	Respiratory failure not fully explained by cardiac failure or fluid overload				
Chest Imaging ^a	Chest imaging findings of new infiltrate(s) consistent with acute pulmonary parenchymal disease				
Oxygenation	Noninvasive Mechanical Ventilation		Invasive Mechanical Ventilation		
			Mild	Moderate	Severe
	Full face-mask bi-level ventilation or CPAP ≥5 cm H ₂ O, PF ratio ≤300, SF ratio ≤264		4 ≤OI<8	8 ≤OI<16	OI ≥16
			5 ≤OSI<7.5	7.5 ≤OSI<12.3	OSI ≥12.3
SPECIAL POPULATIONS					
Cyanotic Heart Disease	Standard preceding criteria for age, timing, origin of edema, and chest imaging with an acute deterioration in oxygenation not explained by underlying heart disease				
Chronic Lung Disease	Standard preceding criteria for age, timing, and origin of edema with chest imaging consistent with new infiltrate and acute deterioration in oxygenation from baseline that meet preceding oxygenation criteria				
Left Ventricular Dysfunction	Standard preceding criteria for age, timing, and origin of edema with chest imaging consistent with new infiltrate and acute deterioration in oxygenation that meet preceding criteria not explained by left ventricular dysfunction				

PARDS, Pediatric acute respiratory distress syndrome; CPAP, continuous positive airway pressure; PF ratio, partial pressure of oxygen (PaO_2) to fraction of inspired oxygen (FiO_2) ratio; SF, saturation fraction ($\text{SpO}_2/\text{FiO}_2$); OI, oxygenation index ($[\text{FiO}_2 \times \text{mean airway pressure} \times 100] / \text{PaO}_2$); OSI, oxygen saturation index ($[\text{FiO}_2 \times \text{mean airway pressure} \times 100] / \text{SpO}_2$).

BOX 65.1 Causes of Acute Respiratory Distress Syndrome

Direct (Pulmonary) Causes

Pneumonia

- Bacterial
- Viral: influenza, respiratory syncytial virus
- Mycobacterial
- Fungal

Aspiration

Drowning

Smoke or chemical inhalation

Pulmonary contusion

Indirect (Nonpulmonary) Causes

Severe sepsis and septic shock

Significant trauma

Severe hemorrhage

Severe pancreatitis

Transfusion reaction

Cardiopulmonary bypass

Thermal burn

FIG. 65.1 Early stage of acute respiratory distress syndrome.

ETIOLOGY

The inflammatory cascade that ultimately results in ARDS can be triggered by a variety of insults that directly or indirectly affect the lung (Box 65.1). Direct pulmonary insults include pneumonia, aspiration, chest trauma, drowning injury, and smoke inhalation. Indirect lung injury may be the result of generalized systemic conditions, such as sepsis, closed head injury, multisystem trauma, transfusion reactions, pancreatitis, and hemorrhagic shock. A study of 146 PARDS cases found that infectious etiologies were the most common causes of ARDS: 35% had bacterial pneumonia, 20% had lung disease due to respiratory syncytial virus (RSV), and 27% had sepsis.⁶⁶ ARDS was due to trauma in only four (3%) pediatric cases.⁶⁶

Bacterial lower respiratory tract infection is the most common inciting event in PARDS, although severe sepsis is often also present.¹²⁰ *Streptococcus pneumoniae* and *Pseudomonas aeruginosa* are bacteria commonly associated with severe pneumonia potentially leading to sepsis and, subsequently, ARDS.¹² Some bacteria may be associated with a higher risk of ARDS than other pathogens because of the production of cytotoxic and chemotactic toxin production.^{78,10}

Viral pneumonia is also an important initiator of ARDS and is frequently not diagnosed due to testing limitations.⁸⁷ RSV infection is one of the most common indications for admission to the pediatric intensive care unit (PICU), especially during the winter months.¹⁷ Although most critically ill children present as severe RSV bronchiolitis, a significant proportion (up to 27%) can present with ARDS; those with preexisting conditions are at the highest risk.⁴⁶ Influenza virus is another important cause of ARDS. In one study, 80% of children admitted to the PICU with influenza developed ARDS.³⁶ A single-center study found that as many as 24% of patients with the 2009 pandemic H1N1 strain developed ARDS.⁹² A less common cause of viral-induced ARDS is coronavirus, particularly the strain that caused the severe acute respiratory syndrome (SARS) outbreak in 2003, which affected adults more severely than children.^{62,63} Bacterial coinfection increases the risk that viral pneumonia will cause ARDS. For example, in patients with the severe pandemic H1N1 viral infection, bacterial coinfection was shown to increase the need for mechanical ventilation, duration of intensive care unit (ICU) stay, and mortality.^{90,93}

In addition to lower respiratory tract infections, severe sepsis is a leading risk factor for indirect ARDS in children.¹²⁰ ARDS has been described following sepsis due to many different organisms and does not seem to be directly related to pathogen-specific factors.⁵⁶ Multiorgan dysfunction and other illnesses associated with sepsis increase the risk

for ARDS, and this risk is further increased by the presence of underlying comorbidities.⁵⁰ In critically ill adults, sepsis is associated with an approximately 40% risk of developing ARDS.⁸⁰ Sepsis appears to be a less common cause of ARDS in pediatric patients; one study found that 15% of PARDS cases were attributable to sepsis.⁶⁶

Limited data exist on the impact of the underlying etiology of ARDS on clinical outcomes in children. In a study of 736 adults with ARDS, patients with sepsis-related ARDS were more likely to have diabetes, longer pre-ICU stay, and higher APACHE III (a measure of severity of illness in critically ill adults) scores in contrast to those who had non-sepsis-related ARDS.⁹⁹ However, after accounting for differences in clinical characteristics, no difference was found in 60-day mortality between patients with sepsis-related ARDS and non-sepsis-related ARDS. Furthermore no evidence exists to suggest that the source of sepsis is an important determinant of mortality in ARDS.⁹⁸ However, genetic differences in the immune regulation underlying responses of the lungs to these precipitating factors do account for some of the differences in the degree of severity in ARDS in individual patients, even when similar risk profiles are present.⁸² One such example of genetic polymorphisms is that related to nuclear factor- κ B (NF- κ B). A deletion polymorphism of the promoter region of this important transcription factor leads to inappropriate upregulation of proinflammatory genes, which has been shown to result in an increase in ARDS severity and mortality.^{3,9}

CLINICAL MANIFESTATIONS

The initial clinical course of ARDS begins with direct or indirect acute injury to the pulmonary parenchyma. In the initial stage, the clinical symptoms and physical findings vary depending on the underlying etiology of the ALI. Children with pulmonary etiologies of ARDS will have predominantly respiratory symptoms; those with nonpulmonary etiologies of ARDS will have symptoms related to the initial insult (e.g., acute abdomen for pancreatitis). Early in the course of lung injury, patients may display mild tachypnea and dyspnea but tend to have normal radiographic findings.

After the inciting event and initial phase, a latent period of variable duration follows. During this latent period, the patient may appear to be clinically stable, but early signs of pulmonary insufficiency develop, as manifested by hyperventilation with hypocarbia and respiratory alkalosis. The chest radiograph may begin to demonstrate a fine reticular pattern related to increases in pulmonary interstitial fluid (Fig. 65.1).³³ As the degree of lung injury worsens, acute respiratory failure follows and is characterized by rapid onset of hypoxemia that is often refractory to supplemental oxygen administration. Diffuse pulmonary edema and worsening compliance cause significant atelectasis and intrapulmonary shunting. Clinically patients develop rapid, shallow tachypnea with increased work of breathing. Subcostal and supraclavicular retractions,

FIG. 65.2 Established acute respiratory distress syndrome.

grunting, and nasal flaring are common. Lung examination usually reveals diffuse crackles. Radiographically bilateral areas of consolidation with air bronchograms reflect alveolar filling and atelectasis (Fig. 65.2). CT may provide additional information.¹⁰² A significant percentage of these children will require endotracheal intubation and mechanical ventilation. However, noninvasive ventilation may be an alternative for a subgroup of patients.⁸³

MORTALITY

Most studies indicate that mortality associated with ARDS is due to nonrespiratory causes.^{72,39} In most cases, early death (i.e., within 72 hours) is caused by the underlying illness or injury, whereas late death (i.e., beyond 72 hours) is caused by infection or multiorgan system failure. Reported mortality rates for children with ARDS vary greatly and range from 8% to 79%.^{14,23,28,49,86,113,118} This variation is likely due to the myriad of underlying causes of ARDS, the differing degrees of ARDS severity, and the presence or absence of concomitant organ failures. ARDS secondary to sepsis appears to confer the highest risk of death, likely due to the systemic dysfunction present at the onset of ARDS symptoms.¹¹⁸ Some of the factors that have been identified as predictors of mortality in PARDS include P/F ratio, oxygenation index, pH, Pediatric Risk of Mortality (PRISM) score (a severity index score commonly used in PICUs), and presence of multiorgan failure.^{40,85} Despite the large reported variation in mortality, it is generally accepted that the overall mortality rate of PARDS is lower than that of the adult population.¹²⁰ Additionally ARDS-related mortality has decreased over the past several years, likely due to improvements in supportive care and the widespread adoption of low tidal volume ventilation strategies, the only mechanical ventilation strategy that has ever been shown to decrease mortality in ARDS in a randomized clinical study.¹¹⁰ This study was conducted in adults and, although the role of low tidal volume ventilation in reducing mortality in pediatric patients is not clear, mortality rates following PARDS have fallen from 80% in the 1980s to approximately 20% in the early 2000s and are potentially under 15% now.¹²⁰

TREATMENT

Goals of treatment of patients with ARDS include treating the underlying disease (when possible), achieving adequate tissue oxygenation, and minimizing ventilator-induced lung injury (VILI). In patients in whom ARDS is secondary to sepsis or bacterial lower respiratory tract infection, prompt administration of appropriate antibiotics is essential.^{61,29} The antimicrobial approach depends on patient-specific risk factors as well as patterns of drug resistance in the community and within a given

hospital. Local rates of cephalosporin-resistant *S. pneumoniae* and methicillin-resistant *Staphylococcus aureus* (MRSA) may necessitate broad-spectrum gram-positive coverage (e.g., vancomycin).^{29,53} Patients with neutropenia or other risk factors for sepsis due to gram-negative pathogens may require extended-spectrum penicillins or cephalosporins as part of their empiric therapy. The mainstay of support in the ARDS patient is the provision of supplemental oxygen and mechanical ventilation. In addition, nonpulmonary organ function must be meticulously maintained to optimize the clinical care of children with ARDS.

Pulmonary Management

Modes of Mechanical Ventilation

Multiple modes of mechanical ventilation are currently used in clinical practice to provide respiratory support for patients with ARDS. Regardless of the conventional mechanical ventilation (CMV) mode used, it is paramount that VILI be minimized by paying meticulous attention to prevention of barotrauma and volutrauma.⁹⁵ Prospective, randomized multicenter studies comparing a pressure-controlled mode to a volume-control mode in the setting of ARDS are limited and have not demonstrated a single ventilatory mode as being superior.^{95,35,84}

However, a landmark study of adults with ARDS published in 2000 did show that low tidal volume mechanical ventilation (6 mL/kg) decreased mortality by 22% and increased the number of ventilator-free days in contrast to a more traditional tidal volume (12 mL/kg).¹¹⁰ This study is the only investigation in either adult or pediatric ARDS that has demonstrated a mortality benefit associated with a specific ventilatory approach. It is important to mention that two pediatric-focused observational studies demonstrated an inverse relationship between delivered tidal volumes and mortality.^{34,54} However, a large retrospective multicenter pediatric study of acute hypoxic respiratory failure did not reveal an association between tidal volume and either mortality or ventilator-free days.¹¹⁹ One must be careful not to make definitive conclusions from these pediatric-based studies, which demonstrate association rather than cause and effect. Without pediatric-specific definitive data, the low tidal volume approach has generally become standard practice in the PICU environment.

In contrast to CMV, high-frequency oscillatory ventilation (HFOV) is an alternative mode that delivers extremely small-volume “breaths” at high rates (5 to 15 Hz [equivalent to 300 to 900 breaths/min]). Although use of HFOV has become commonplace in pediatrics, the only definitive study of this method in PARDS is a crossover trial conducted more than 20 years ago that showed improved oxygenation and a reduction in the need for supplemental oxygen at 30 days.⁶ The adult-based OSCAR and OSCILLATE ARDS trials of HFOV have led to a negative view of this ventilatory modality. OSCAR found no difference in mortality between HFOV and CMV.¹¹⁷ OSCILLATE was prematurely stopped due to higher mortality with HFOV compared to control ventilation.³⁸ The RESTORE HFOV study compared the length of mechanical ventilation in pediatric subjects managed with early (within 24 to 48 hours of intubation) HFOV compared to patients receiving CMV or late HFOV by means of a propensity score analysis. After adjusting for risk category, early HFOV was associated with an increased length of ventilation but not increased mortality as compared to patients managed with CMV/late HFOV. However, this study raises an important question of whether the increased length of ventilation with early HFOV is directly related to HFOV or rather to the manner in which this modality was used.¹¹ Unfortunately, pediatric clinicians are left to determine whether or not to use HFOV based on their interpretation of the available data as well as their clinical experience. In general, despite the lack of definitive evidence in support of HFOV in pediatrics, it has become an often-used technique in the management of PARDS.⁸⁹

Positive End-Expiratory Pressure

Positive end-expiratory pressure (PEEP) is the constant pressure applied to the airways and alveoli during exhalation and helps maintain alveolar patency and restore functional residual capacity. PEEP is typically titrated to a level that allows adequate oxygenation at an acceptable FiO₂.

The ARDS Network investigated the optimal PEEP-FiO₂ approach for adult patients with ARDS and showed that both “lower” and “higher”

PEEP strategies produced similar survival rates.¹⁸ The results of this study suggest that as long as adequate PEEP is applied, higher levels are not necessary but are acceptable. Once appropriate PEEP is applied to maintain the lungs at an ideal volume, further increases in PEEP in an attempt to reduce the FiO_2 do not lead to an improved outcome.⁷ A follow-up meta-analysis of almost 2300 patients demonstrated that patients with pure ALI (i.e., recruitable lung) benefited from a higher PEEP strategy, whereas those without recruitable lung did not.¹⁴ Based on these data, a strategy that individualizes PEEP based on the specific clinical circumstances seems warranted. As long as alveolar collapse is minimized, the balance between PEEP and FiO_2 can be left to the discretion of the clinician.

Permissive Hypoxemia and Permissive Hypercapnia

Every child with ARDS is hypoxemic by definition. Prolonged administration of high concentrations of oxygen can damage lungs due to the formation of oxygen free radicals. Human and animal studies suggest that a prolonged FiO_2 of greater than 0.60 should be avoided to prevent oxygen-induced pulmonary damage.⁵² However, the exact FiO_2 cutoff for oxygen toxicity in the ARDS patient, especially in children, remains unknown and may be less than 0.60. Increases in the set PEEP may allow for a reduction of the delivered FiO_2 .

In the setting of ARDS, improved oxygenation has not been associated with improved outcomes. This finding was best demonstrated in the ARDS Network low tidal volume study, in which the control (12 mL/kg) group demonstrated improved oxygenation for the first 72 hours of mechanical ventilation but ultimately had a higher mortality in contrast to the lower tidal volume (6 mL/kg) group.¹¹⁰ In a pediatric study of 470 children, no correlation was found between oxygenation or ventilation measured during the first 14 days of PICU admission in survivors or nonsurvivors of pediatric ALI.¹⁰⁸ Other studies in PARDS have demonstrated short-term improvements in oxygenation parameters with no difference in mortality.^{30,31} The ideal target for oxygenation in ARDS remains controversial, but it is clinically reasonable to accept an SaO_2 of less than 90% as long as tissue oxygen delivery is adequate. This concept of accepting lower arterial oxygen saturations is termed *permissive hypoxemia*.^{1,86} In general, FiO_2 , PEEP, and other ventilatory parameters should be set to optimize oxygen delivery with tolerance of lower oxygen saturations to allow for minimization of VILI.⁹⁵ Specific recommendations for a lower level of acceptable oxygen saturations cannot be made.

Permissive hypercapnia is another strategy commonly used in patients with ARDS. Hypercapnia is a consequence of low tidal volume ventilation, and limited evidence suggests that low-volume, pressure-limited ventilation with permissive hypercapnia may improve outcomes in patients with ARDS.^{47,48} In a 10-year study, Milberg and colleagues reported an association of permissive hypercapnia with decreased mortality.⁷¹ Recent data from a laboratory model of ischemia-reperfusion ALI indicate that hypercapnic acidosis is protective and that buffering of the hypercapnic acidosis actually attenuates these protective effects.⁶⁰ Animal models have also suggested that permissive hypercapnia may attenuate lung damage in sepsis-induced ARDS.^{22,51} Although permissive hypercapnia may inhibit the immune response to some degree,⁵⁹ this results in decreased inflammation with an associated decrease in ALI.²¹ Inhibition of the immune system is of particular concern in patients with sepsis, but administration of antibiotics appears to prevent these deleterious effects.^{20,76,77} These findings, along with data demonstrating worsening mortality with each hour in which antibiotics are delayed in septic patients,⁵⁸ reinforce the need for early administration of antibiotics in the management of pediatric sepsis and ARDS.¹⁵ Despite these potential benefits and evidence suggesting that respiratory acidosis is not harmful, the exact degree of hypercapnia that can be safely tolerated remains controversial. Most of the undesirable effects of hypercapnia are reversible and minor when pH is greater than approximately 7.20.³⁷ Further clinical studies looking at the role of permissive hypercapnia in sepsis-related lung injury are needed given the increasing preclinical evidence of its potential therapeutic role.

Adjunctive Therapies

Corticosteroids

Given that inflammation is the cornerstone of the pathophysiology of ARDS, corticosteroids have therapeutic potential as immunomodulatory

or antiinflammatory agents. An inherent difficulty in summarizing the use of corticosteroids is the significant variability in the timing and dose of steroids used in the various studies. The timing of steroids in published clinical studies of adults ranges from 72 hours to 4 weeks from the onset of ARDS, and the doses of methylprednisolone (or its equivalent) range from 1 mg/kg per day to 120 mg/kg per day.⁸¹ Meta-analyses of corticosteroid use within the first 2 weeks in adults with established ARDS demonstrated that steroids may reduce mortality and reduce total days of mechanical ventilation.^{81,106} A more recent meta-analysis of patients with ARDS due to community-acquired pneumonia found no difference in mortality for patients treated with steroids or placebo but did find that steroids reduced length of hospital stay and the duration of mechanical ventilation.¹⁰¹ Although few studies evaluating steroids have included children, a recent prospective observational study of 283 PARDS patients found that steroids were associated with a longer duration of mechanical ventilation with no difference in mortality.¹¹⁶ Additionally, based on current data, corticosteroids do not appear to have a role in preventing ARDS.⁸¹ The use of steroids has not been associated with an increase in secondary infections.^{81,106}

Inhaled Nitric Oxide

Pulmonary vascular dysfunction is an important component of the pathophysiologic process of ARDS.¹⁹ The impact of ARDS on pulmonary vascular tone has led to an extensive investigation of inhaled nitric oxide, a potent vasodilator that works exclusively in the pulmonary vasculature, as a potential therapeutic option. Studies of inhaled nitric oxide for PARDS have demonstrated temporary improvement in oxygenation acutely but not improved survival.^{2,31,30} The largest pediatric inhaled nitric oxide study to date involved 108 children.⁵¹ Because of the crossover design, the study was not able to describe mortality results, but it did demonstrate that the groups of children who may acutely benefit most are immunocompromised patients and those with greater severity of hypoxemia.

A recent Cochrane Database Systematic Review looking at 14 randomized controlled trials concluded that inhaled nitric oxide cannot be recommended for either children or adults with ARDS because it resulted in transient improvement in oxygenation without mortality benefit.⁴ Furthermore it appeared that inhaled nitric oxide may increase the risk for renal impairment among adults with ARDS. Except for the potential treatment of documented pulmonary hypertension and/or severe right ventricular dysfunction, the administration of inhaled nitric oxide for ARDS cannot be recommended based on the available data.¹⁰⁵

Surfactant Replacement

In ARDS, injury occurs to type 2 pneumocytes, resulting in decreased production of surfactant. This injury has prompted studies examining the possibility of the effectiveness of surfactant replacement in the management of ARDS. A study of 153 pediatric patients reported that exogenous surfactant acutely improved oxygenation and significantly decreased mortality in infants and children with ALI.¹¹³ There were no significant decreases in duration of mechanical ventilation, length of PICU admission, or length of hospital stay. The results of this study are controversial because a significantly higher number of immunocompromised patients (i.e., with a higher expected mortality) were included in the control group.²⁵ Randomized trials in adults found that, for 450 adults with ARDS randomized to surfactant or placebo, there was no difference in mortality and, for 308 adults randomized to calfactant or placebo, there was no improvement in oxygenation or survival.^{103,115} More recent pediatric studies that included a total of 274 patients have also shown that surfactant does not improve mortality in infants and children.^{107,114} Surfactant replacement is not currently recommended for the treatment of PARDS.⁴⁵

Nonpulmonary Supportive Management

Fluid Balance

Initial aggressive fluid resuscitation is important in maintaining hemodynamics and improving clinical outcomes in patients with shock.⁹⁶ However, once hemodynamics are restored, overhydration may lead to pulmonary edema. Fluids should be carefully titrated and fluid status monitored while normalizing the patient's intravascular volume status

and maintaining adequate cardiac output.⁵ The ARDS Network conducted a study to investigate conservative and liberal fluid management strategies in adult patients with ARDS.¹¹² In this study, a difference of 6000 mL was seen in the 7-day cumulative fluid balance between the two groups, with patients in the conservative fluid management group having improved lung function and shorter duration of mechanical ventilation and ICU length of stay. In critically ill children, the role of fluid balance is less conclusive. Although some studies demonstrate that fluid balance has an impact on oxygenation and morbidity,^{5,49} other prospective pediatric studies have shown otherwise.⁸⁸ The Pediatric Acute Lung Injury and Sepsis Investigators (PALISI) Network investigators showed that cumulative fluid input and output did not affect the speed of weaning from mechanical ventilation or extubation outcomes.⁸⁸

Sedation and Neuromuscular Blockade

Appropriate sedation and analgesia are important in children who are on mechanical ventilation. Prolonged sedation and neuromuscular blockade have been associated with worse clinical outcomes, and the long-term effects of sedative medications are unknown.^{7,42,65} However, a recent study demonstrated that early neuromuscular blockade improved survival in adults with ARDS.⁷⁹ In this study of 340 adults with ARDS, the use of cisatracurium for 48 hours improved 90-day survival by nearly 1.5 times compared to placebo without an increase in muscle weakness. In contrast, growing evidence in adults indicates substantial benefits associated with sedation weaning and promotion of early mobilization.^{43,73} In children, a sedation weaning protocol was not found to change the duration of mechanical ventilation, PICU or hospital lengths of stay, or in-hospital mortality.²⁴ Given the lack of consistent evidence in both adults and children, the use of neuromuscular blockade in children with ARDS remains controversial. Overall use of sedatives and neuromuscular blocking agents should be driven by a balance between maintaining adequate gas exchange and the potential adverse effects of critical illness weakness and myopathy.

Nutrition

As a general approach, adequate nutrition should be provided to optimize caloric intake and avoid a negative nitrogen balance. However, few studies examining the effects of nutrition in children with ARDS have been conducted. Clinical guidelines with regard to nutritional support of critically ill children are, at best, supported by small, randomized trials with reasonable risk for bias in their results.⁷⁰ Although a growing number of studies are investigating the potential utility of nutritional supplementation in ARDS, the results have not been consistent or encouraging. Using bronchoalveolar and plasma biomarkers as their end points, investigators examining the effect of omega-3 oil on adults with ARDS did not note any difference in IL-8, IL-6, and leukotriene B4 levels between patients with and without supplementation.¹⁰⁴ This was further supported by a recent clinical study that was stopped early for futility.⁹⁴ This study of twice-daily supplementation of omega-3 fatty acids within 48 hours of onset of ARDS showed a trend toward longer duration of mechanical ventilation and higher mortality in the treatment group.⁹⁴

Patient Isolation

Even though infectious etiologies are the most common cause of ARDS in children, routine isolation of all ARDS patients is not warranted. In certain infective etiologies such as viruses (e.g., influenza, RSV, adenovirus), resistant bacteria, and mycobacteria (e.g., tuberculosis), appropriate isolation measures should be instituted.¹⁰⁰

Rescue Therapies

Some patients with severe ARDS become refractory to maximal therapies and are unable to achieve acceptable therapeutic goals while avoiding oxygen toxicity or intolerably high airway pressures. In these circumstances, extracorporeal membrane oxygenation (ECMO) has increasingly been used as a rescue modality for these patients.

ECMO involves withdrawing blood from the patient by a mechanical pump and directing it to a membrane oxygenator, where oxygenation and removal of carbon dioxide occur before the blood is returned to the patient. In refractory ARDS patients, venovenous ECMO is commonly

used, which involves blood being withdrawn from the patient via a cannula placed in a central vein and returned to the venous system. Cardiac function must be sufficient to circulate this returned blood systemically to the body. ECMO has been used successfully in a wide range of clinical circumstances and is a viable treatment strategy in adults and children with refractory ARDS.^{16,44} Traditionally ECMO has been implemented in patients with an anticipated mortality that is extremely high, exceeding 80% to 90% in many circumstances, but reported survival from the Extracorporeal Life Support Organization (ELSO) registry for adults and children with ARDS is currently 50% and 65%, respectively.^{16,32} In the past decade, use of ECMO has continued to increase, as evidenced by reports from the 2009 H1N1 influenza A pandemic.^{27,74,75,109} A more detailed discussion of ECMO support for pediatric and adult ARDS patients is beyond the scope of this chapter.²⁶

CONCLUSION

ARDS represents a complex syndrome of varying pulmonary and nonpulmonary etiologies. Although much progress has been made in better understanding the pathophysiology of ARDS, the only ventilatory strategy that has been demonstrated to improve clinical outcome is low tidal volume ventilation. Effective treatment of the underlying etiology can reduce mortality related to the infectious process and likely reduces continued lung damage due to ongoing inflammation.^{118,29} It is anticipated that future clinical studies will combine therapeutic strategies instead of simply focusing on a single intervention. Although meticulous balance is important in each organ system, limited data exist regarding the optimal supportive management strategies for children with ARDS. Current approaches largely represent clinical experience and extrapolation of the available data from the adult population. Hopefully the recent recommendations and comments made by the PALICC group will help to prompt future, more definitive research of the PARDS.

Approach to Infections in the Fetus and Newborn

Gail J. Harrison

This chapter provides an overview and approach to the diagnosis and management of the more common infections that occur in the fetus and newborn infant. Details about how each organism affects the fetus and newborn, as well as information on diagnosis and management, are covered in the pathogen-specific and disease-specific chapters of this edition.

VIRAL INFECTIONS OF THE FETUS AND NEONATE

Viral infections are an important cause of fetal and neonatal morbidity and mortality. The cumulative frequency of viral infections in the fetus or newborn infant may be as high as 6% to 8% of all live births, whereas systemic bacterial disease occurs in only 1% to 2% of neonates. Viral infections of the fetus and newborn may be divided into congenital, perinatal or natal, and postnatal time periods of acquisition.

Pathogenesis

Congenital Viral Infections

Congenital viral infections are transmitted to the developing fetus during a maternal infection. Most congenital viral infections are from maternal primary infections, but some viruses (cytomegalovirus [CMV]) may be transmitted to the fetus during a recurrent (reactivation or reinfection) maternal infection.⁸ Congenital viral infections can result in resorption of the embryo; spontaneous abortion or miscarriage; stillbirth; congenital malformation; prematurity; intrauterine growth restriction (IUGR); or acute disease apparent in utero, at birth, or shortly thereafter. Congenital infection with Ebola virus is uniformly fatal.^{4,13,31} In contrast, most congenital CMV infections are asymptomatic in the fetal or neonatal period yet may be associated with persistent postnatal infection, sequelae later in life, or a normal infant with no apparent sequelae.

Most fetal infections are preceded by a systemic viral infection in the mother, with hematogenous spread of the virus to the placenta and subsequently to the fetus (Fig. 66.1). Ascending infection through amniotic membranes also may occur while the fetus is still in utero. With most viruses well known to cause fetal infection—CMV, rubella virus, herpes simplex virus (HSV), varicella zoster virus (VZV), Ebola virus, Zika virus, Dengue, and vaccinia virus—placental involvement by the virus also has been documented (Table 66.1).^{4,13,31} Viruses may reach the fetal circulation by (1) replication through the layers of the placenta; (2) production of virus-induced vascular lesions in the placenta, resulting in abnormal communications between the maternal and fetal circulation; or (3) diapedesis of virus-infected maternal leukocytes through the layers of the placenta to the fetal circulation.

Developmental malformations also may occur. Rubella virus is the classic known teratogen, causing disturbances in organogenesis, cardiac disease, and cataracts.⁹ VZV and Zika virus have been shown to cause limb hypoplasia and developmental malformations of the eye and brain.^{11,19,20} Other viruses that result in congenital abnormalities, such as CMV and HSV, usually cause inflammatory, destructive lesions of already developed organs. Type B coxsackieviruses and other enteroviruses have been associated with a variety of congenital malformations of the heart, and mumps has been linked to endocardial fibroelastosis. Chikungunya virus also may cause congenital infection and disease.¹⁷

Damage to the fetus also may occur in the absence of actual fetal viral infection as a result of severe systemic illness in the mother, such as measles or influenza, or alteration of placental function.

Natal or Perinatal Viral Infections

Natal or perinatal infections are the result of exposure of the newborn to virus replicating in the maternal cervicovaginal tract (i.e., CMV, HSV, or hepatitis B virus) or perirectal area (e.g., enteroviruses). Natal or perinatal infections with some viruses can cause acute systemic illness leading to death, persistent infection with late sequelae (HSV, HBV), self-limited disease with no discernible damage (CMV), or asymptomatic infection (see Fig. 66.1 and Table 66.1). Because the incubation periods of HSV and enteroviruses are short, acute postnatal disease may appear in the neonate within 5 to 7 days of age. In contrast, the incubation periods of CMV and hepatitis B virus (HBV) are longer, and clinically apparent disease from perinatal exposure, if it occurs, may not be observed for several weeks or even months after birth. Persistent postnatal infection can occur after perinatal infection with CMV, HSV, and HBV.

Postnatal Viral Infections

Postnatal infections in the neonate may be transmitted to the neonate from the mother, family members, caretakers in extended family, health care workers, outbreaks in neonatal care units, or community exposures (see Fig. 66.1). Neonatal infections and hospital-associated outbreaks of enterovirus and parechovirus, respiratory syncytial virus (RSV), rotavirus, adenovirus, rhinovirus, parainfluenza virus, human metapneumovirus, and influenza virus infection have occurred. In addition, health care-associated HSV infections have occurred in neonates (see Table 66.1). Although the maternal respiratory and gastrointestinal tracts are the most common sites from which virus can be transmitted to the neonate postnatally, other viruses, including human immunodeficiency virus (HIV), human T-cell leukemia virus types 1 and 2 (HTLV I and II), CMV, West Nile virus, rubella virus, hepatitis C virus (HCV), Zika virus, and HBV, have been recovered from breast milk. HSV and VZV lesions on the breast of a mother also may be a source of transmission of virus for the breastfeeding neonate, even though these viruses probably are not present in the breast milk. Finally, HIV, CMV, and HBV have been transmitted to newborn infants by blood transfusion. Although most postnatal infections are acute, self-limited processes, severe disease and fatalities have been reported, especially in preterm infants infected with CMV, enteroviruses, HSV, adenoviruses, or RSV, and persistent postnatal infection may occur with CMV and HBV.^{6,5}

Approach to Diagnosis

Evaluation of the Mother

Fetal viral infection may be suspected if the mother is exposed to or experiences an infection with a virus known to transmit to the fetus. A history of recent illness, travel, or exposures to the mother should be obtained to uncover circumstantial evidence for a viral infection in the fetus or newborn. For example, the occurrence of maternal viral illness with an associated maculopapular rash suggests rubella or enterovirus or Zika virus infection in the neonate, exposure to mosquitoes suggests St. Louis encephalitis virus, West Nile virus, or Zika virus, ulcerative genital lesions suggest HSV, and heterophile-negative infectious mononucleosis is suggestive of CMV.^{25,26} Hemorrhagic fever after travel to Africa suggests Ebola virus.^{4,11,21} Maternal rash with arthralgias also may be caused by parvovirus B19, especially if there is recent exposure to fifth disease in the community. Since viral infections in the mother may be asymptomatic, the absence of symptoms in the mother does not rule out the possibility of a viral infection in the neonate.

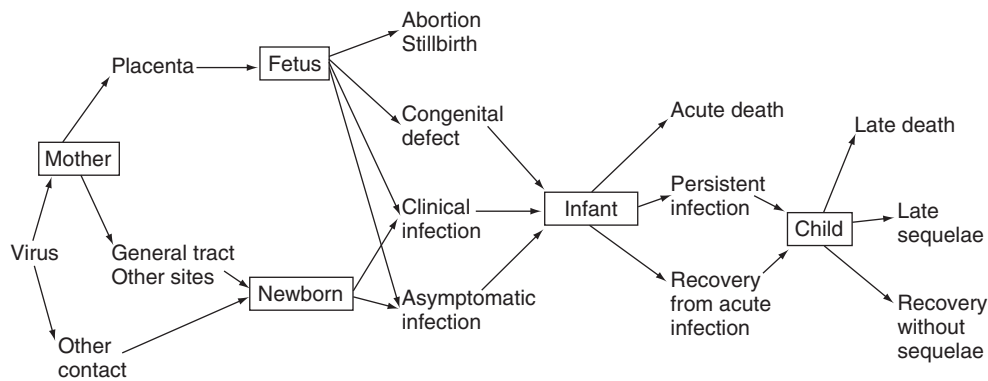

FIG. 66.1 Pathogenesis of viral infections in the fetus and newborn.

++, Major demonstrated route; +, minor demonstrated route; (+), suggested route, few supporting data; –, route not demonstrated.

Clinical Features in Fetus and Newborn

Abnormalities detected on routine fetal ultrasound also may suggest fetal infection. These findings include IUGR; microcephaly; cerebral ventriculomegaly or hydrocephalus; cataracts; hepatosplenomegaly; hepatic or intracranial calcifications; and cortical maldevelopment syndromes such as polymicrogyria, hydrocephalus, microcephaly, in utero central nervous system (CNS) vasculitis, echogenic bowel, fetal ascites, cardiomegaly, congestive heart failure, fetal hydrops,

enlarged or swollen placenta, or polyhydramnios or oligohydramnios.^{19,20} Intrauterine cardiac abnormalities, myocarditis, and heart failure may be associated with HIV, parvovirus B19, mumps virus, CMV, Zika virus, or adenovirus, and cardiac structural defects may be associated with rubella virus. Limb deformities or dysplasias, especially if they are associated with eye or CNS abnormalities, may be caused by intrauterine VZV or HSV infection and possibly Zika virus.

In more than 80% of CMV, 60% of rubella virus, and most HBV infection in the neonate are asymptomatic. In contrast, less than 1% of HSV infections and no Ebola virus infections are subclinical in the neonate.

Clinical manifestations of viral disease in the neonate may provide helpful clues to the specific etiologic agent. The presence of cataracts, congenital heart disease, bone lesions, or microphthalmos is highly suggestive of rubella, whereas chorioretinitis, cerebral calcifications, and hydrocephaly are more common with congenital infection with CMV, lymphocytic choriomeningitis virus (LCMV), Zika virus, or HSV. The features in neonates with perinatal or postnatal enterovirus, HSV, or adenovirus disease resemble those associated with bacterial sepsis: lethargy or irritability, fever or hypothermia, respiratory distress, cyanosis, anorexia or vomiting, hepatomegaly, seizures, or abnormal movements.^{6,5} Laboratory abnormalities in disseminated viral disease may show neutropenia, lymphocytosis, lymphopenia, thrombocytopenia, elevated liver transaminases, hyperbilirubinemia, and cerebrospinal fluid (CSF) pleocytosis. Aseptic meningitis in the neonate may be caused by perinatal or postnatal infection with HSV1 or 2, enteroviruses, or parechoviruses. In neonates with persistent severe viral infections that are slow or minimally responsive to antiviral therapy, a primary immune deficiency disorder of T-, B-, or natural killer (NK)-cell function should be considered.

Differential Diagnosis

The differential diagnosis in a fetus or newborn infant with a suspected viral infection includes but is not limited to bacterial or fungal sepsis, toxoplasmosis, syphilis, erythroblastosis fetalis, metabolic inborn errors of metabolism, genetic chromosomal abnormalities, and other forms of congenital malformations.

Laboratory Diagnosis

Prenatal diagnosis of fetal viral infection may be established by testing amniotic fluid for viral culture and polymerase chain reaction (PCR) or by fetal blood sample for viral-specific immunoglobulin (Ig)M and PCR studies. The placenta may also be sent for histopathologic studies.

In neonates, urine, saliva, and blood for CMV; throat, cataracts, and occasionally CSF or urine for rubella; skin vesicles, blood, CSF, conjunctivae, throat, stool, and urine for HSV; throat, stool, urine, CSF, or blood for enteroviruses; and skin vesicles and blood for VZV should be sent for virus isolation or virus detection by PCR. In addition, isolation or molecular detection by PCR of virus can be attempted from biopsy or autopsy specimens. Electron-microscopic examination of vesicle fluid or tissue can demonstrate typical herpesvirus particles in both HSV and VZV infection but cannot distinguish between the two. Dried

blood spots archived after completion of newborn screening for metabolic and immunodeficiency disorders may be retrieved with maternal permission from state newborn screening agencies and tested for the presence of viral DNA.^{2,3} Such approaches have reliably allowed the retrospective diagnosis of congenital CMV. Research evaluating urine and saliva as screening specimens for congenital CMV infection have also been conducted.^{2,3,8}

Three approaches can be used to make a serologic diagnosis of viral infection in a newborn infant: (1) assay of maternal serum and serum specimens from the infant at birth and at 5 to 6 months of age for antiviral antibody (predominantly IgG activity), (2) assay of neonatal serum for IgM antibody against a specific viral agent, and (3) assay of neonatal serum for quantitative IgM levels, a nonspecific indication of antigenic challenge in utero.²⁶ Maternal IgG, antibody against viruses to which the mother has been exposed, passes transplacentally, beginning at midgestation. Peak levels are reached in fetal serum at the time of birth (umbilical cord blood); they decline to undetectable levels by the time that the infant reaches 6 to 12 months of age, depending on the virus. Maternal IgM antibody normally is not passed transplacentally, but a fetus challenged in utero with a virus can have specific IgM antibodies against the viral agent as well as elevated levels of the total IgM fraction. Often a fetus with detectable virus-specific IgM will have severe in utero disease caused by the virus.

Treatment

Intravenous acyclovir followed by long-term oral suppression with oral acyclovir is the mainstay for antiviral treatment of neonatal herpes simplex virus infection.^{6,5,15,23} Congenital CMV disease, especially if it is severe or involves the CNS or sensory organs such as the eye and ear, may be treated with intravenous ganciclovir or oral valganciclovir.^{8,14,23} Neonates with influenza virus may receive antiviral medications such as oseltamivir, and ribavirin for severe RSV disease.

BACTERIAL DISEASES OF THE FETUS AND NEWBORN

Worldwide, millions of neonates die every year of bacterial infection.¹⁶ In the United States, the infant mortality rate is approximately 6.85 infant deaths/1000 live births. Neonatal bacterial sepsis corresponds to the eighth leading cause of fatality. The incidence of neonatal sepsis ranges from 1 to 8/1000 live births, with the higher figures corresponding to developing countries. Low birth weight, male sex, and congenital malformation are important risk factors. Extreme prematurity is the greatest risk factor for early-onset sepsis and is associated with an increased risk for having adverse outcomes. The highest age-specific incidence of bacterial meningitis appears to occur during the first month of life.

Epidemiology and Pathogenesis

The human birth canal is host to large numbers of aerobic and anaerobic bacteria, *Mycoplasma*, *Ureaplasma*, *Chlamydia*, fungi, yeast, and viruses. *Staphylococcus epidermidis*, lactobacilli, diphtheroids, and α -hemolytic streptococci are found in 50% to 100% of vaginal cultures of pregnant women and constitute the predominant aerobic flora. Significant but less common isolates include *Gardnerella vaginalis*, *Proteus*, and *Klebsiella* spp. and group B and D streptococci; *Staphylococcus aureus* and miscellaneous organisms, such as *Citrobacter*, *Acinetobacter*, and the *Campylobacter* group, are identified even less commonly. Approximately 85% of women with genital colonization by anaerobes harbor *Bacteroides* spp., including *Bacteroides fragilis* in a third of cases. Anaerobic streptococci, *Peptostreptococcus* and *Peptococcus*, are found in approximately 40% of women, and *Clostridium* is present in 20%. Uncommon anaerobic isolates include *Veillonella*, *Bifidobacterium*, and *Eubacterium*.

Certain microorganisms are associated with the occurrence of stillbirths. Among these bacterial agents are *Escherichia coli*, group B streptococci (GBS), *Ureaplasma urealyticum*, *Listeria monocytogenes*, and *Treponema pallidum*.

Streptococcus agalactiae, or GBS, is a major pathogen for the neonate, causing both early-onset sepsis and late-onset disease, usually meningitis, but also other manifestations (Box 66.1). The acute early-onset form

BOX 66.1 Common Bacterial Pathogens Causing Neonatal Sepsis

Gram-Negative Organisms

Escherichia coli
Haemophilus influenzae
Citrobacter
Enterobacter spp.
Pseudomonas spp.
Acinetobacter
Neisseria meningitidis

Gram-Positive Organisms

Group B streptococci (*Streptococcus agalactiae*)
Viridans streptococci
Enterococci
Streptococcus pneumoniae
Other streptococci
Listeria monocytogenes
Coagulase-negative staphylococci
Staphylococcus aureus

of GBS disease can be caused by any of the group B types (B_I to B_{VIII}), and the specific B type causing disease in the infant usually is found in the maternal vaginal tract. GBS meningitis is caused almost exclusively by the B_{III} organism. These organisms also may be acquired from nonmaternal sites. Clusters of three or four cases of GBS meningitis have occurred in nurseries during short intervals, suggesting that health care-associated outbreaks may occur. The administration of intrapartum antibiotics, such as ampicillin, has reduced the incidence of early-onset GBS disease in neonates. *E. coli* is the other important agent implicated in neonatal bacterial disease, including sepsis, meningitis, and urinary tract infection, with an annual incidence of approximately 6.8/1000 live births; it is the most common gram-negative bacterium causing meningitis during this period.¹ Ampicillin-resistant and multidrug-resistant *E. coli* strains have emerged. Neonatal colonization with *E. coli* often results from maternal transmission during delivery. *Klebsiella pneumoniae* is another important neonatal pathogen causing sepsis and meningitis, with an incidence of between 4.1 and 6.3/1000 live births and fatality rates of 18% to 68%. It is the second most frequent gram-negative organism associated with late-onset sepsis in developed nations. *L. monocytogenes* is a foodborne colonizer of the human gastrointestinal tract, and one of the host factors that increases the risk for *Listeria* infection and disease is pregnancy. Perinatal infection constituted 34% (470/1378) of cases of listeriosis. Transmission to the fetus in utero may produce granulomatous fetal disease and an early-onset sepsis syndrome or a late-onset meningitis.

S. aureus is another important bacterial neonatal pathogen, causing sepsis, meningitis, osteomyelitis, and abscesses in newborns postnatally. Since the 1980s, epidemic and endemic colonization and disease of the newborn infant with community-acquired and hospital-acquired methicillin-sensitive (MSSA) and MRSA have become commonplace. *S. epidermidis* and other coagulase-negative staphylococci also are important neonatal pathogens and a common cause of late-onset sepsis and infections associated with indwelling devices and necrotizing enterocolitis. They are the most common species of the normal flora on the skin, nasal mucosa, and umbilicus of the newborn. The ubiquitous presence of the organisms and their tolerance to drying and temperature changes contribute to the presence of coagulase-negative staphylococci in neonates. *Enterococcus faecalis* and *E. faecium* are members of the group D streptococci (enterococci), are normal inhabitants of the gastrointestinal tract, and can cause invasive disease in the neonate, usually urinary tract infections, sepsis, and meningitis. These bacteria are the third most frequent gram-positive organisms associated with late-onset sepsis. Outbreaks of bacteremia and meningitis caused by *E. faecium* resistant to ampicillin and vancomycin have also been reported in neonates.

Neonatal Sepsis

Sepsis neonatorum, or sepsis of the newborn, is a bacterial disease of infants 30 days of age or younger, most often in the first week of life.²²

The major signs and symptoms of sepsis in the newborn relate to disturbances in thermoregulation, respiration, heart rate, and gastrointestinal function; abnormalities in temperature regulation, either hypothermia or hyperthermia; tachypnea; grunting respirations; cyanosis; intercostal and substernal retractions; and apnea. A heart rate persistently in excess of 160 beats per minute or above average for age and gestation can be a sensitive indicator of early-onset neonatal sepsis. Other early signs of neonatal sepsis include poor feeding, regurgitation, vomiting, weak sucking, abdominal distention, diarrhea, jaundice, and, rarely, gallbladder distention.

Neonates may have cutaneous findings with onset of sepsis neonatorum, which may provide clinical clues for the cause of the condition. Such findings include cellulitis or abscesses (*Staphylococcus* or *Streptococcus*); papular (i.e., listeriosis), vascular, or bullous lesions (i.e., *Pseudomonas*); and exfoliative dermatitis (i.e., phage group II staphylococcal disease). Jaundice develops in approximately one-third of infants with sepsis and can also occur in infants with urinary tract infection. Occasionally, jaundice is the only sign of infection and occurs in septic infants regardless of the type of bacterial pathogen.

Bacterial sepsis in the newborn may be caused by almost any gram-positive or gram-negative organism.^{1,22} The most commonly identified bacteria include GBS, group A streptococcus (GAS), and group D streptococcus (GDS), including the enterococci and viridans streptococci. In addition *Streptococcus pneumoniae* may cause severe illness in the neonate. The gram-positive rod *L. monocytogenes* is also a well-recognized cause of neonatal sepsis. The staphylococci, including community-acquired and hospital-acquired MSSA and MRSA and coagulase-negative staphylococci may cause sepsis in the newborn. Gram-negative enteric organisms, such as *E. coli* and *K. pneumoniae*, are common causes of neonatal sepsis. In addition, other gram-negative organisms, such as *Enterobacter cloacae* and *Acinetobacter* spp., may cause sepsis in the neonate. *Haemophilus influenzae* also has been isolated from neonates with sepsis.

Abnormalities in the white blood cell (WBC) count may be observed, with elevation, left shift with neutrophil predominance, leukemoid reaction, or neutropenia, with thrombocytopenia. The presence of severe thrombocytopenia, or less than 50,000 cells/mL, within 72 hours of birth is an uncommon occurrence and may be caused by early bacterial infection (e.g., GBS sepsis) or congenital viral infection (CMV or HSV). Late-onset thrombocytopenia is often caused by bacterial sepsis or necrotizing enterocolitis. In these cases, platelets fall rapidly, with a nadir at 24 to 48 hours, to counts less than 50,000 cells/mL and tend to persist until the infection is controlled. Slow recovery of platelet counts over a period of 1 to 2 weeks is common.

Elevation of C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) also may occur.²⁴ The ESR in infected patients generally is elevated above the normal range of 1 to 2 mm/h at 12 hours of age to 17 to 20 mm/h at 14 days of age. Elevated rates usually are not observed until 24 to 48 hours after clinical signs of disease first occur.

Antimicrobial therapy, administered intravenously, directed against the usual pathogens suspected and then adjusted based on culture results is recommended. For infants whose initial bacterial cultures are sterile after 48 to 72 hours of incubation and the clinical suspicion for bacterial infection is low, antimicrobial therapy can be discontinued. If no pathogen has been isolated but bacterial sepsis cannot be excluded, a negative CRP test at 72 hours can help support the decision to discontinue antibiotics.

In addition to antibiotics, supportive care with careful attention to fluid and electrolyte balance; correcting hypoxia, acidosis, hypoglycemia, and other metabolic abnormalities; and providing nutritional support is necessary. Human immunoglobulin for intravenous use in septic neonates appears to be safe but not convincingly proved to be beneficial in randomized clinical trials. In neonates with primary immunodeficiency syndromes involving B-cell function that cause reduced levels of immunoglobulin, replacement therapy with immunoglobulin may be needed. Other supportive therapeutic options for critically ill neonates include extracorporeal membrane oxygenation and immunomodulating

strategies (e.g., anticytokine agents, steroids, pentoxifylline, and nitric oxide inhibitors).

Prevention of neonatal sepsis is a priority for clinicians and physician research scientists. Intrapartum chemoprophylaxis given to women at 35 to 37 weeks' gestation with proved GBS colonization reliably prevents colonization of the newborn in the postpartum period and reduces early-onset sepsis caused by GBS. Therefore universal prophylaxis of all pregnant women with GBS colonization is now recommended and is the current cornerstone for prevention of early-onset GBS disease.^{1,30} Clinical trials evaluating maternal immunization with GBS as a way to prevent neonatal GBS disease are under way. Currently, no licensed vaccine against GBS exists; however, many experts feel this strategy, when available, will be the most effective and sustainable long-term preventive strategy for neonatal GBS disease.

Prevention of early sepsis caused by gram-negative bacilli by administration of intrapartum aminoglycosides is important in developing areas of the world where these organisms are prevalent, but no standardized guidelines exist.

Prevention of late-onset infection, as opposed to early-onset disease, in neonates by the administration of intravenous immunoglobulin to preterm babies has undergone intense clinical scrutiny, but consensus of summaries of clinical trial evidence does not support its routine use at this time.³⁰

Bacterial Meningitis

As many as a fourth of neonates with bacterial sepsis have a simultaneous meningeal infection.^{10,27} The early signs and symptoms of neonatal meningitis frequently are indistinguishable from those of septicemia and other disorders occurring in the neonatal period. The most frequent signs of neonatal meningitis are temperature instability, respiratory distress, irritability, lethargy, and poor feeding or vomiting. GBS occasionally has been reported to manifest as hydrocephalus without other signs of infection. Signs of meningeal involvement, such as a stiff neck, bulging fontanelle, seizures, and opisthotonos, usually are not present in neonates with meningitis. Therefore newborns being evaluated for sepsis usually should undergo examination of CSF, especially if antimicrobial therapy is to be instituted.

Abnormal CSF parameters with elevated WBC count with polymorphonuclear leukocyte predominance, hypoglycorrachia (low glucose), elevated protein concentration, and positive Gram-stained smear with a positive bacterial culture are the classic and definitive methods to diagnose bacterial neonatal meningitis. However, bacterial meningitis may be present even in the absence of these abnormalities.

Ventriculitis may complicate neonatal bacterial meningitis.^{12,27} Obstructive ventriculitis is suspected when the head circumference increases dramatically, the anterior fontanelle is persistently full, CSF cultures are persistently positive, and examination of ventricular fluid shows elevation of WBCs with polymorphonuclear predominance, presence of bacteria on Gram-stained smear, and positive culture. Brain imaging by cranial ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI) with contrast material may show enhancement of the lining tissue of the ventricles or brain abscess formation.

Ampicillin and gentamicin or cefotaxime, administered in meningeal doses, are recommended for initial empiric treatment of neonatal meningitis for most neonates. If there is an indwelling device, such as a ventricular-to-peritoneal shunt in place, or a Gram-stained smear shows gram-positive cocci, staphylococci should be suspected and vancomycin administered. If a multidrug-resistant gram-negative organism is suspected or present, then cefepime or meropenem may be indicated. Neonates with bacterial meningitis usually should undergo repeat CSF examination and culture 24 to 48 hours after initiation of therapy. In neonates with bacterial meningitis caused by *Citrobacter diversus* or *Cronobacter (Enterobacter) sakazakii*, cranial CT or brain MRI imaging should be obtained early because of the frequent association with brain abscess. For neonatal meningitis caused by *Flavobacterium meningosepticum* isolates, combined use of parenteral vancomycin and rifampin has been suggested as the best therapeutic option.

Penicillin G or ampicillin is preferred for GBS meningitis, ampicillin for *L. monocytogenes* and enterococci, ampicillin plus an aminoglycoside or cefotaxime for coliforms, and ceftazidime or ticarcillin-clavulanate

and an aminoglycoside for *Pseudomonas* infections. The duration of systemic therapy in neonatal meningitis depends on the causative agent and the time necessary to sterilize CSF cultures. For meningitis caused by GBS or *Listeria*, approximately 2 weeks of therapy usually is satisfactory. Because delayed sterilization is a common occurrence in infants with gram-negative enteric disease, systemic therapy is given for 3 weeks and, in some babies, for additional weeks. Intraventricular therapy is not routinely recommended for management of neonatal meningitis caused by gram-negative enteric bacilli.³ However, on an individualized basis, intraventricular therapy may be of benefit in certain patients with obstructive ventriculitis caused by persistent or resistant organisms.

Acute complications of bacterial meningitis include communicating and noncommunicating hydrocephalus, subdural effusions (~1% of patients), deafness, and blindness. Ventriculitis occurs in approximately 70% of neonates with coliform meningitis. Brain abscess is an infrequent complication, except in infants with *C. diversus* or *C. (E). sakazakii* meningitis, in whom abscess develops approximately 70% of the time. A 30% to 50% incidence in neurologic sequelae has been reported in surviving infants. Although neurologic deficits may be obvious in some infants at discharge, most babies appear “well” at this time. Only after prolonged and careful follow-up do the perceptual difficulties, behavioral problems, and other subtle neurologic signs become apparent. Within 4 to 6 weeks of recovering from meningitis, hearing should be evaluated by evoked response audiometry.

Otitis Media

Otitis media is diagnosed infrequently in neonates because of the paucity of clinical findings and the difficulty of examining an infant's tympanic membrane. The onset of illness associated with otitis media is insidious, and the most common manifestations are rhinorrhea, irritability, and failure to thrive. Fever higher than 38°C (100.4°F) is a rare finding. The presence of lethargy, hypotonia, hypothermia, high fever, or jaundice suggests the otitis media is complicated by bacteremia or meningitis.

The cause of neonatal otitis media is similar to that observed in older infants and children. *S. pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis* account for more than 50% of cases. Approximately 10% to 15% of neonates have disease caused by coliforms, GBS, or *S. aureus*.

Diarrheal Disease

Diarrhea can be a nonspecific symptom of sepsis or urinary tract infection in a newborn infant. Bacteria that may cause diarrhea in the neonate include enteropathogenic *E. coli*, *Vibrio cholerae*, some *E. coli* nonenteropathogenic strains, *Vibrio parahaemolyticus*, *Aeromonas*, *Shigella*, *Salmonella*, *Campylobacter*, and *Yersinia*. Some diarrheal episodes in neonates probably can be caused by *Clostridium difficile*. Shigellosis in a newborn may occur as a diarrheic or dysenteric syndrome or may be evidenced only by a septic- or toxic-appearing infant. *Salmonella* may cause sepsis and bacterial meningitis in the neonate. Neonates with diarrhea caused by *Salmonella* should be carefully evaluated for systemic illness and treated with intravenous antibiotics.

Urinary Tract Infections

The incidence of bacteriuria and urinary tract infection in newborn infants ranges from 0.5% to 1% for term infants and is approximately 3% for premature infants. Most infants with significant bacteriuria are asymptomatic or have nonspecific signs and symptoms. The neonate may also appear septic or may have decreased activity, feeding problems, and the other constitutional signs that are seen with infections of other organ systems. Jaundice, hepatomegaly, and thrombocytopenia may be observed in a few infants with urinary tract infection; these findings are associated with septicemia or cholestatic hepatitis in some babies.

E. coli is the most common etiologic agent of urinary tract, with *Proteus*, *Klebsiella*, and *Pseudomonas* spp. also important pathogens. Gram-positive bacteria, with the exception of enterococci, rarely are encountered as pathogens for the urinary tract. Neonates with renal abscess caused by *S. aureus* or gram-negative enteric bacteria have been reported in the literature.

The diagnosis of urinary tract infection is confirmed by examination, urinalysis, and culture of urine. Blood and urine should be obtained for culture from all newborn infants with suspected or proved urinary

tract infection before antimicrobial therapy is initiated. A repeat urine culture performed 48 to 72 hours after initiation of appropriate therapy should be sterile or show a substantial reduction in the bacterial count. Infants with persistent bacteriuria should be evaluated for the possibility of resistant organism, obstruction, or perinephric abscess. In uncomplicated disease, therapy usually is continued for a period of 7 to 10 days. Approximately 1 week after discontinuance of therapy, a repeat urine culture may be performed.

Neonates with documented infection should undergo radiologic evaluation of the urinary tract. Renal sonogram may be performed to evaluate the possibility of gross congenital abnormalities of the urinary system.

Suppurative Arthritis and Osteomyelitis

Osteomyelitis and suppurative arthritis are unusual in the first 4 weeks of life. Bone and joint infections can be difficult to detect in neonates and young infants. The predominant organisms are *S. aureus* (both MSSA and MRSA), GBS, and gram-negative enteric organisms such as *Klebsiella*, *Proteus*, and *E. coli*. Gonococcal arthritis and tenosynovitis were common occurrences in neonates in previous decades and still may be seen in developing countries. Other bacteria associated infrequently with newborn infection in the bones and joints are *Salmonella* and *Pseudomonas*.

Two distinct clinical syndromes that may be associated with osteomyelitis in the newborn period have been described. The first form presents as a local infection, in which the earliest sign of bone and joint infection in newborns is failure to move an extremity spontaneously or apparent pain on movement without systemic evidence of infection. Swelling, erythema, and heat localized to the affected part are late findings. Multiple bones or joints can be involved, especially when disease is caused by *S. aureus*. The second form of presentation is characterized by disseminated, systemic manifestations of sepsis; only later are multiple sites of bone and visceral involvement noted. Another unique clinical presentation of osteomyelitis in the newborn is maxillary bone involvement by osteomyelitis, usually caused by GBS or *S. aureus*. Maxillitis or osteomyelitis of the superior maxilla is an unusual form of bone infection in newborn infants. Blood should be obtained for culture from all infants with osteomyelitis or septic arthritis. A recommended sample is percutaneous needle aspiration of intraarticular pus in patients with suspected suppurative arthritis or aspiration of sequestrum, abscess, or lytic bone lesion in those with suspected osteomyelitis. If pus or tissue is obtained, the material should be Gram stained and cultured.

Selection of initial antimicrobial therapy is guided by preliminary identification of the pathogen from stained smears of material obtained by needle aspiration. Surgical removal of infected material is an integral part of treatment, even in the neonate. Open drainage is essential for managing septic hip disease. The inflammation in osteomyelitis or septic arthritis can occupy the epiphyseal and metaphyseal sides of the growth plate and result in ischemia and necrosis of the plate and permanent orthopedic damage. For other joints, repeated daily evacuation of fluid with a needle and syringe usually is adequate. In patients with osteomyelitis, the subperiosteal space and the metaphysis should be drained if pus is obtained during diagnostic aspiration. Antimicrobial treatment of neonatal musculoskeletal infections caused by *S. aureus* or gram-negative organisms is continued for a minimum of 4 to 6 weeks, depending on clinical response.

Conjunctivitis and Orbital Cellulitis

Infections of the eye of the newborn can be caused by a variety of microorganisms, including *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *S. aureus* (MSSA or MRSA), and *P. aeruginosa*. Other less frequently encountered organisms included *M. catarrhalis*, *Pasteurella multocida*, *Haemophilus*, and *Neisseria meningitidis*. Nonbacterial organisms, including *Chlamydia* and HSV, should be considered in the differential diagnosis of neonatal conjunctivitis. Any infant with a conjunctival discharge should be evaluated carefully to determine the cause. Three tests should be performed: Gram and methylene blue stain of the exudate, culture of the exudate, and Giemsa stain and culture for *Chlamydia*, if available, of scrapings made from the lower palpebral conjunctiva after

the exudate has been removed. The results of the stained smears and cultures determine the appropriate therapy.

Funisitis and Omphalitis

If inflammation of the cord alone is present, funisitis is diagnosed. It is characterized by a wet, malodorous umbilical cord and stump, without surrounding cellulitis. The umbilical cord may be colonized with numerous different potential bacterial pathogens, some of which, like GAS, may not only cause inflammation in the cord of the neonate but also produce nursery outbreaks of disease.

Omphalitis, or infection of the umbilicus, has many causes and occurs more frequently in low-birth-weight infants and those with complicated deliveries. The incidence is estimated to be approximately 2%, and symptoms start at an average age of 3 days. Culture and susceptibility test results are necessary for the selection of an appropriate antibiotic. *S. aureus* is the most frequent pathogen isolated, followed by GAS, GBS, and gram-negative rods. Some of the complications secondary to omphalitis reported in the literature are bacterial sepsis, spontaneous evisceration of the small bowel through the umbilical cicatrix, necrotizing fasciitis, small bowel obstruction, peritonitis, and superficial, retroperitoneal, or hepatic abscesses.

Breast Abscess

Breast abscesses are encountered most frequently during the second or third week of life and are more common findings in girls, particularly those older than 2 weeks. The disease does not appear to occur in premature infants, presumably because of underdevelopment of the mammary glands in these infants. Bilateral disease is a rare event.

The major clinical finding is swelling of the affected breast with or without accompanying erythema and warmth. Systemic manifestations are uncommon occurrences, and only a fourth of patients have low-grade fever. *S. aureus* is the major pathogen, but coliform bacteria, such as *E. coli* and *Salmonella*, and GBS have become more common causes in the past decade. Blood cultures should be obtained, but bacteremia is a rare finding in this condition. If the patient has only mild cellulitis and no discernible fluctuance, antibiotic treatment alone may suffice. Fluctuant abscesses should be drained.

Suppurative Parotitis

Suppurative parotitis of the newborn usually is easy to recognize, although occasionally it is confused with infection of a preauricular or superior anterior cervical lymph node. Infection occurs more commonly in low-birth-weight infants than in term infants and more commonly in boys. Dehydration predisposes to stasis of parotid secretions and subsequent infection. Bilateral infection is a rare event.

Although *S. aureus* (MSSA and MRSA) accounts for most cases, disease may be caused by coliform bacteria, *Pseudomonas*, pneumococci, and GAS. The clinical manifestations include fever, anorexia, irritability, and failure to gain weight. Erythema, swelling, and tenderness over the involved gland may occur. The diagnosis can be confirmed by expressing pus through the parotid duct or by needle aspiration of a fluctuant area. Gram staining of this material helps identify the causative agent. Selection of antimicrobial therapy should be based on interpretation of the Gram-stained smear of expressed pus. In most cases, antibiotic therapy alone suffices, and surgical incision and drainage are unnecessary. Response to therapy generally is rapid. Most patients require only 7 to 10 days of therapy until healing is complete.

Scalp Abscess

Scalp abscesses usually are a complication of fetal monitoring with scalp electrodes. The number of vaginal examinations, use of more than one electrode, and fetal scalp blood sampling are risk factors for the development of scalp abscesses. Pathogens incriminated include staphylococci, gonococci, and gram-negative enteric bacteria. A polymicrobial flora, including anaerobic organisms, frequently is isolated in scalp abscesses caused by electronic fetal monitoring electrodes. Incision and drainage of the infected site along with antibiotics for 7 days usually is sufficient for most term neonates with uncomplicated scalp abscesses caused by susceptible bacteria. Scalp lesions associated with scalp electrodes that do not show bacteria on Gram stain or culture

may be caused by HSV and should be evaluated with viral culture of lesions and surfaces, examined by HSV DNA PCR of blood and CSF, and treated with intravenous acyclovir.

Pneumonia

Neonatal lower respiratory tract bacterial infections may be acquired congenitally or postnatally. Congenital or perinatal infection results from transplacental transfer of the agent (i.e., congenital infection) or from inhalation of infected amniotic fluid (usually associated with prolonged rupture of membranes) or infected vaginal secretions during delivery.

Common bacterial pathogens causing postnatally acquired pneumonia are *S. aureus*, coliform bacilli, and *Pseudomonas*. These infections occur sporadically or epidemically and may be acquired from the community in otherwise healthy neonates or are health care–associated in hospitalized neonates. The physical findings of pneumonia are variable. Flaring of the alae nasi, rapid respirations, and sternal and subcostal retractions are common findings. Coughing indicates lower respiratory tract involvement; brassy coughing is found frequently in viral disease. Crackles or wheezes usually can be heard on deep inspiration (or when the baby is crying) but may be absent early in disease. Cultures of blood and material from the trachea frequently help in defining the etiologic agent of neonatal pneumonia. A chest radiograph should be obtained for all babies with suspected lower respiratory tract disease. Radiographic evidence of pneumonia may exist in the absence of specific physical findings. Although the cause of neonatal pneumonia usually can be determined from a radiograph, certain radiologic patterns are associated with specific diseases. With acute-onset GBS disease, the radiograph may mimic one showing hyaline membrane disease. A consolidating bronchopneumonia with pneumatoceles, with or without empyema, suggests staphylococcal disease. When a lobar infiltrate is associated with expansion of the lobe, *K. pneumoniae* infection should be considered. A miliary type of bronchopneumonia in a septic neonate is characteristic of listeriosis or, less commonly, mycobacterial disease.

Pertussis is also an important cause of respiratory disease and pneumonia in the neonate. The onset of disease generally is in the second to sixth weeks of life; the earliest onset reported was at 10 days of age. Pertussis should be suspected when an infant has a paroxysmal cough with excessive mucus. Because apneic spells are common occurrences, newborns with pertussis should be admitted to the hospital for initial management. PCR-based methods are currently recommended to confirm the diagnosis.

YEAST AND FUNGAL INFECTIONS OF THE FETUS AND NEONATE

The improved survival of preterm infants since the early 1980s has resulted in the emergence of yeasts and fungi as significant neonatal pathogens. *C. albicans* remains the most frequently isolated pathogenic yeast overall, but other *Candida* spp., especially *C. parapsilosis*, *C. tropicalis*, *C. krusei*, *C. lusitanae*, *C. haemulonii*, and *C. auris*, and less common pathogenic yeasts, such as *Malassezia*, *Trichosporon*, *Rhodotorula*, and *Pichia* (formerly *Hansenula*), have increased in frequency. The incidence of invasive fungal disease, often with fatal outcomes, caused by *Aspergillus* and Zygomycetes (*Mucor*, *Rhizopus*, *Rhizomucor*, and *Absidia*) also has increased in neonates, especially infants who were born prematurely or with an inherited metabolic disorder or primary immunodeficiency.

Neonatal Candidiasis

The species isolated most frequently from neonates is *C. albicans*, which represents approximately 40% to 60% of isolates from neonates with systemic disease and is the most common *Candida* spp. associated with NICU outbreaks.²⁹ *Candida* spp. other than *C. albicans* have become increasingly more prevalent, however, and in some NICUs may be isolated more frequently than *C. albicans*. Among these organisms, *C. parapsilosis* is the most common, followed by *C. tropicalis*; both of them have caused outbreaks in NICUs. *C. glabrata*, *C. guilliermondii*, *C. lusitanae*, and *C. krusei* also have caused invasive disease in neonates. Most recently, *C. haemulonii* and *C. auris* have emerged as a neonatal pathogen and caused

an outbreak in an NICU.²⁸ Several risk factors consistently have been associated with systemic candidiasis, the most common being prematurity and very low and extremely low birth weight (VLBW and ELBW), with attendant impairment of host defense mechanisms; indwelling intravenous catheters; and prolonged use of broad-spectrum antimicrobial therapy—in particular, third-generation cephalosporins that suppress normal gastrointestinal flora. Neonatal candidiasis may be congenital or acquired and ranges from commonly encountered benign oral and cutaneous candidiasis to systemic infection with candidemia to more severe and often fatal disseminated candidiasis.

Oral candidiasis is the most common form of infection involving *Candida* spp. Cutaneous candidiasis typically is manifested by erythematous, vesiculopustular lesions found primarily on the skin of the perineum, axilla, and intertriginous areas. The periumbilical area also can be involved. In VLBW and ELBW premature infants, seemingly benign mucocutaneous lesions, including lesions in the perineum or diaper area, may progress rapidly to invasive dermatitis, producing cutaneous scales, crusting, erosions, ulcerations, or extensive maceration of skin, and result in a potentially lethal systemic candidiasis. Scattered, faint, erythematous maculopapular lesions of the skin may be an expression of a serious disseminated candidiasis. Chronic mucocutaneous candidiasis may be diagnosed in an otherwise well-appearing infant if *Candida* infections of the skin, mucous membranes, and nails persist or recur despite administration of antifungal therapy. These neonates have a congenital defect in T-lymphocyte function specific to *Candida* spp.

Congenital candidiasis may cause fetal infection with onset of premature labor or intrauterine demise; it may be evident at birth, or it may appear within the first 24 to 48 hours of life. Term and preterm neonates may be affected. Maternal risk factors include a history during pregnancy of *Candida* vaginitis, use of antibiotics, retained intrauterine contraceptive device, cervical cerclage, and prolonged rupture of fetal membranes, although none of these factors may be present in the history. Congenital systemic candidiasis may manifest as life-threatening, early-onset sepsis syndrome, especially in premature neonates with septic shock, pneumonia, or meningitis; it also may be accompanied by leukocytosis or neutropenia, or it may mimic congenital leukemia. Twins may be affected, sometimes with different *Candida* spp., manifestations, and outcomes for each twin. Premature neonates with congenital candidiasis often have more severe disease, with positive blood cultures and evidence of disseminated disease, including meningitis. The umbilical cord from a fetus or newborn with congenital candidiasis may show *Candida* funisitis with yellow-white nodules and fungal microabscesses; the placenta also may have nodules and shows chorioamnionitis on histologic examination.

Acquired systemic candidiasis includes catheter-associated sepsis, in which *Candida* is isolated from the blood of infants who have central venous catheters but no evidence of focal infection or disseminated. The organ involved most frequently in systemic candidiasis seems to be the kidney. *Candida* may be isolated from the urine of 73% of neonates with systemic candidiasis with positive blood cultures, but only 5% to 15% of such neonates have documented *Candida* pyelonephritis with renal infiltration, mycetoma, or renal abscess. The kidney seems to be particularly vulnerable to the formation of renal cortical abscesses and obstructive masses, which usually occur at the ureteropelvic junction. A neonate with persistently positive urine or blood cultures, hypertension, renal insufficiency or acute renal failure, or oliguria or anuria should undergo ultrasound imaging to determine the presence of a bezoar-associated obstructive uropathy, which requires immediate attention. Urinary catheters or nephrostomy tubes may become colonized with *Candida* and result in secondary infections that may range from asymptomatic to invasive disease with obstruction.

Candida meningitis may occur in the absence of positive blood cultures; CSF pleocytosis may be minimal or absent, and elevated protein or hypoglycorrhachia is an inconsistent finding. Gram-stained smears of CSF rarely reveal budding yeast, even when CSF cultures are positive for *Candida*. Fernandez and associates,¹⁰ in a 10-year review of candidal meningitis in 23 infants in an NICU, reported that pleocytosis occurred in only 39% of infants and hypoglycorrhachia occurred in 25%, despite

a positive CSF culture for *Candida* in 74% of infants. The remaining neonates are diagnosed when a positive blood culture occurs with an abnormal but culture-negative CSF. *Candida* also may colonize and infect external ventricular drains placed for management of hydrocephalus.

Candida endocarditis may occur in neonates with normal hearts and in neonates with structural heart disease and as a postoperative complication of cardiac surgery. It usually occurs in premature neonates with persistent candidemia associated with an indwelling vascular catheter. Most neonates with *Candida* endocarditis have structurally normal hearts, however, and not all reported cases in neonates have been associated with vascular devices. The presentation of *Candida* endocarditis in neonates may be acute and associated with an episode of persistent candidemia, or late onset, often discovered weeks or months after a presumably silent or resolved episode of candidemia. Cardiac murmurs may be absent. Intracardiac vegetations on the mitral, tricuspid, and aortic valves or the presence of a right atrial mass in association with persistently positive blood cultures for *Candida* strongly supports the diagnosis of endocarditis.

Eye disease may occur in 3% to 11% of neonates with systemic candidiasis; figures as high as 45% have been reported. Candidal eye disease may complicate systemic candidiasis in term, near-term, and preterm infants.

Osteoarthritis is a rare manifestation of systemic candidiasis in neonates. It may occur temporarily associated with persistent candidemia or as a late complication, weeks to months later, after apparent resolution of an episode of candidemia. In addition to premature infants, newborns with underlying inherited disorders of metabolism also may be at increased risk.

Intraabdominal infections, including enteritis, necrotizing enterocolitis (NEC), and peritonitis, and intraabdominal and hepatosplenic abscesses are estimated to occur in 8% of neonates with invasive systemic candidiasis. *Candida* peritonitis and sepsis may complicate surgical procedures performed on the intestine for congenital bowel atresias or bowel perforation associated with NEC. Distinct from NEC is idiopathic spontaneous focal intestinal perforation (SFIP), which occurs rarely in VLBW infants and has been associated with systemic candidiasis in half of cases.

Acquired pulmonary candidiasis with pneumonia may occur in 8% to 10% of ventilated premature neonates and must be differentiated clinically and radiographically from asymptomatic *Candida* colonization and pneumonia caused by other pathogens.

Diagnosis

Congenital or acquired cutaneous candidiasis may be diagnosed by the presence of budding yeast organisms in scrapings of skin lesions, with the species involved established by culture. Invasive dermatitis caused by *Candida* can be differentiated from benign cutaneous dermatitis by skin biopsy. Histopathologic evidence of organisms beyond the stratum corneum is evidence of more serious invasive dermatitis that leads to potentially fatal systemic candidiasis.

Congenital or acquired systemic candidiasis in a fetus or neonate is established by isolation of *Candida* spp. in culture from a normally sterile body fluid, such as amniotic fluid, urine, blood, or CSF, or from an involved site, such as joint or bone or from abscess. Culture of CSF should be performed if candidemia is documented, even if CSF indices are normal. If the urine grows *Candida*, renal or systemic infection is suggested.

Routine laboratory evaluations may support the diagnosis of systemic or invasive candidiasis. Persistent thrombocytopenia is a frequent early finding in infants with systemic candidiasis. Additional laboratory tests, such as a complete blood cell count, liver function tests, and determination of serum glucose, blood urea nitrogen, and creatinine, may be helpful in assessing the degree of systemic involvement.

Treatment

Oral candidiasis or thrush in an otherwise healthy infant is treated with oral nystatin suspension or gentian violet. Superficial cutaneous candidiasis in an otherwise healthy neonate is treated with topical nystatin cream or powder. Cutaneous candidiasis that persists or evolves into

invasive candidiasis requires systemic antifungal therapy, usually with amphotericin B or fluconazole.

Congenital candidiasis usually requires only topical antifungal therapy in an otherwise healthy newborn; neonates who have pulmonary involvement or who are preterm should receive systemic antifungal therapy because they are at greater risk for dissemination and a poor outcome. In these instances, amphotericin B or fluconazole may be used for approximately 10 to 25 days, until clinical signs and symptoms have resolved.

Prompt systemic antifungal therapy, usually with amphotericin B or fluconazole, is indicated if even a single blood culture from a neonate is positive for *Candida* spp. In addition to removal of the catheter, systemic antifungal therapy should be administered for at least 10 to 14 days. If the peripheral blood culture also is positive for *Candida* spp., or end-organ disease is present, dissemination via the bloodstream may have occurred, and most experts recommend duration of antifungal therapy to be at least 25 to 30 days. Isolation of *Candida* spp. from a urine specimen obtained by sterile technique denotes invasive renal or systemic disease and requires further evaluation and systemic antifungal therapy. In some patients, medical therapy alone may eradicate the *Candida* infection, even if partial obstruction is present. Some neonates may require an urgent surgical or endoscopic procedure, however, to relieve the obstruction and restore renal function. Duration of antifungal therapy required for cure may range from 25 to 42 days or longer and should be guided by microbiologic cure and resolution of lesions by imaging studies.

Treatment of meningoencephalitis caused by *Candida* spp. in a neonate usually requires systemic therapy for at least 30 days; longer courses of treatment may be required if ventriculitis or brain abscesses or nodules are present.

Treatment of endocarditis or septic thrombophlebitis caused by *Candida* spp. requires prolonged antifungal treatment, at least 30 days and usually 42 to 60 days, depending on clearance of candidemia, clinical progress, and resolution of intracardiac vegetations or lesions as documented by echocardiography. Consultation with a cardiologist or cardiovascular surgeon is recommended. If septic thrombophlebitis with vascular abscess is present or an enlarging valvular mass obstructs blood flow, surgical intervention may be considered. Reports of resolution of endocarditis with medical therapy alone suggest, however, that it may be a valid option to consider, especially for neonates who are hemodynamically stable, with right-sided, nonvalvular lesions.

Treatment of eye disease, such as endophthalmitis, requires systemic antifungal therapy for 25 to 42 days, and consultation with an ophthalmologist is recommended to assess the extent of disease, presence or progression of comorbid retinopathy of prematurity, and response to therapy.

Treatment of osteoarthritis caused by *Candida* spp. usually requires prolonged duration of systemic antifungal therapy (≥ 42 days). Aspiration or surgical drainage by an orthopedic surgeon may be necessary if there is an infected joint or bone abscess.

Peritonitis associated with NEC or SFIP usually requires at least 25 days of systemic antifungal therapy, but longer duration may be required if intraabdominal abscesses develop. Surgical management of SFIP also differs from that of NEC; simple surgical procedures, such as suturing or resection with primary anastomosis, may be all that is required for treatment of SFIP, whereas NEC may require extensive bowel resection.

Duration of systemic antifungal treatment for pulmonary candidiasis is not well established. Treatment should be guided by clinical and radiographic improvement; however, 25 days is likely to be adequate for most patients.

Prevention

Single-center and cohort studies and a large, multicenter, randomized, double-blind, placebo-controlled trial have shown that fluconazole prophylaxis (administered daily, every other day, or twice weekly either orally or intravenously for 4 to 6 weeks after delivery) reduces *Candida* colonization, invasive candidiasis, or mortality rates in high-risk, VLBW premature neonates weighing less than 1500 g.⁷ Emergence of fluconazole-resistant *Candida* spp., including *C. krusei* and *C. parapsilosis*, may occur.

Also disease caused by invasive yeasts other than *Candida* spp. may occur. An outbreak of *Rhodotorula mucilaginosa*, a fluconazole-resistant yeast, occurred more recently in a NICU that routinely administered prophylactic fluconazole.

Invasive Yeasts Other Than *Candida*

Congenital and perinatal infections with the encapsulated yeast *Cryptococcus neoformans* have been reported. *Malassezia* spp. frequently colonize the skin of neonates and may cause invasive disease, such as skin disorders (e.g., pustulosis) and bacteremia.

Pichia (formerly *Hansenula*) *anomala* and *P. ohmeri* may cause infection in preterm VLBW neonates and infants with severe combined immunodeficiency. Invasive diseases in preterm neonates include bloodstream infections, sepsis syndrome, abscesses, and meningitis with ventriculitis. *Trichosporon beigelii* has caused invasive dermatitis, late-onset sepsis, pulmonary infiltrates, and urinary tract infections in VLBW preterm neonates with intravascular catheters. It also may cause endophthalmitis and endocarditis. *T. asahii* infection in neonates has been reported as well. *Rhodotorula* spp. are another emerging opportunistic yeast that has caused catheter-associated bloodstream infections in neonates.

Invasive Fungal Diseases

Congenital and Perinatal Transmission

Fetal demise, congenital infection, and perinatal transmission associated with the endemic dimorphic fungi *Coccidioides immitis* and *Blastomyces dermatitidis* have been described. Published case reports are very rare, however.

Acquired Invasive Fungal Disease

Invasive fungal disease acquired by VLBW or ELBW premature neonates involves primarily the skin, lungs, or gastrointestinal tract. Because many of the invasive fungi that affect neonates also are angioinvasive, sepsis syndrome with hematogenous dissemination to lung, liver, spleen, CNS, and eye may occur rapidly.

Aspergillus. *Aspergillus* spp. include *Aspergillus flavus*, *A. fumigatus*, *A. glaucus*, *A. nidulans*, *A. niger*, and *A. terreus*. *Aspergillus* spp. frequently are found in the environment and the hospital. Diseases associated with *Aspergillus* infection of the neonate include primary cutaneous aspergillosis or invasive dermatitis, pulmonary aspergillosis, and disseminated aspergillosis. Disseminated disease may involve the heart, liver, spleen, lungs, CNS, or eye.

Zygomycetes (Absidia, Rhizopus, Mucor, and Rhizomucor). Zygomycosis, a term preferred now over mucormycosis, usually is caused by the following species of fungi: *Absidia* (*A. corymbifera*), *Rhizopus* (*R. arrhizus*, *R. microsporus*), *Mucor* (*M. amphibiorum*, *M. circinelloides*, *M. hiemalis*, *M. indicus*, *M. racemosus*, *M. ramosissimus*), and *Rhizomucor* (*R. pusillus*, *R. miehei*, *R. variabilis*). Zygomycosis in a neonate usually manifests during the second and third weeks of life. The Zygomycetes are angiotrophic and aggressively invade blood vessels very early in the disease process. Invasion of blood vessels leads to thrombosis, infarction, and tissue necrosis; destruction of local tissue can be extensive, and the fungus may disseminate throughout the body and CNS. The most common presentation of invasive zygomycosis in neonates is primary cutaneous disease. Cutaneous zygomycosis usually begins at an area of minor skin trauma or at the site of intravenous catheter insertion that has come in contact with adhesive tape or bandages, first appearing as a cluster of necrotic vesicles or scales that then rapidly progresses to extensive necrotizing cellulitis. Gastrointestinal zygomycosis in a premature neonate often mimics NEC clinically. Rhinocerebral zygomycosis classically manifests in diabetics with ketoacidosis, but it also may affect neonates with conditions associated with metabolic acidosis and premature infants. The fungus enters via the nasal passages and invades the sinus cavities and orbits, spreading to the CNS by fungal thrombosis of cavernous sinus and internal carotid artery. Pulmonary zygomycosis also may occur, either as a primary pneumonia with consolidation and necrosis or secondary to vascular dissemination from a cutaneous or gastrointestinal source. Disseminated zygomycosis is a fatal fungal sepsis syndrome, usually involving all major organ systems and the CNS.

Treatment

Invasive disease of the neonate caused by fungi is treated with antifungal agents. The choice of antifungal agents available to treat invasive fungal disease of the neonate include the traditional polyene antibiotics, nystatin and amphotericin B deoxycholate, and the pyrimidine analog 5-FC, as well as lipid formulations of amphotericin B, first-generation triazoles (fluconazole and itraconazole), second-generation triazoles (posaconazole, ravuconazole, and voriconazole), and echinocandins (caspofungin, micafungin, and anidulafungin). The choice of which antifungal agent to administer and the duration of treatment should be guided by the reported susceptibility pattern of the fungus, and dosages should be based on available pharmacokinetic information for neonates.

CONGENITAL TOXOPLASMOSIS

Congenital toxoplasmosis results from placental infection that develops after primary maternal infection with *Toxoplasma gondii* and subsequent hematogenous spread to the fetus.¹⁸ Many neonates with congenital toxoplasmosis are seemingly asymptomatic at birth. The most characteristic clinical findings, frequently referred to as the classic triad of congenital toxoplasmosis, are chorioretinitis, intracranial calcifications, and hydrocephalus. They are seen in approximately 86% (chorioretinitis), 37% (intracranial calcifications), and 20% (hydrocephalus) of symptomatic infants. These conditions often are accompanied by a combination of signs and symptoms, including anemia (59%), jaundice (43%), splenomegaly (41%), seizures (41%), fever (40%), hepatomegaly (34%), lymphadenopathy (32%), microcephaly (9%), and eosinophilia (9%).

The diagnosis of congenital toxoplasmosis can be established by isolating the organism from infected body fluids and tissues, such as the placenta, amniotic fluid, fetal blood obtained by cordocentesis, umbilical cord blood, infant blood, and CSF. Alternatively a diagnosis can be established by histopathologic examination of the placenta in which tachyzoites are revealed. PCR has been used successfully to detect *Toxoplasma* DNA in amniotic fluid, placenta, CSF, and fetal and infant blood. The most practical and widely used method of establishing the diagnosis is by testing maternal and newborn blood for serologic evidence of *Toxoplasma* infection by measuring *T. gondii*-specific IgG and IgM antibodies. Consultation with a recognized reference laboratory for toxoplasmosis testing is recommended (Toxoplasmosis Serology Laboratory, Palo Alto Medical Foundation, 860 Bryant Street, Palo Alto, CA 94301; 415-326-8120).

Treatment with spiramycin of an acutely infected woman during pregnancy may prevent transmission of the infection to the fetus. Treatment during the first year of life with pyrimethamine, sulfadiazine, and leucovorin is effective for acute disease and improves long-term outcome in congenital toxoplasmosis.¹⁸

Routine serologic screening of women during pregnancy has been an effective means of prevention in France and Austria, and it has been advocated in other areas where the incidence of congenital toxoplasmosis remains high. Another focus of prevention should be on educating women of child-bearing age to avoid cat feces in litter boxes, outdoor sandboxes, and gardens and avoid ingestion of raw meat and mutton.

CHLAMYDIA, MYCOPLASMA, AND UREAPLASMA INFECTIONS IN THE NEONATE

C. trachomatis is a cause of neonatal conjunctivitis and perinatally acquired infant pneumonia. The introduction of systematic screening and treatment of pregnant women has resulted in a dramatic decrease in the number of perinatal chlamydial infections in developed countries. However, in countries in which pregnant women are not screened routinely, including many developing countries, *C. trachomatis* remains the most frequent cause of neonatal conjunctivitis.

Mycoplasma hominis, *Ureaplasma urealyticum*, and *U. parvum* are the genital mycoplasmas with clinical significance in neonatal disease. Vertical transmission of *Ureaplasma* spp. and *M. hominis* from a colonized mother to her newborn may occur in utero or during delivery. The roles of *Ureaplasma* spp. and *M. hominis* in neonatal disease continue to be investigated and defined.

Primary Immunodeficiency Diseases

Ivan K. Chinn • Javier Chinen • William T. Shearer

Primary immunodeficiency diseases (PIDDs) can be defined as congenital disorders caused by an intrinsic molecular defect that alters the development or function of the immune system. As a consequence, patients with these conditions display increased susceptibility to infections, neoplasia, and autoimmunity. More than 300 PIDDs have been recognized, and many of the gene defects responsible for the immunologic phenotypes have been identified.¹⁷ Previously considered to be uncommon, PIDDs have been estimated to occur at a minimum incidence of 1 per 10,000 live births. A 2007 US survey of 10,000 households, however, reported a prevalence of 1 in every 1200 people for clinically diagnosed PIDD,¹⁸ suggesting that these conditions occur even more frequently than often suspected. A more recent survey of pediatricians in the United States demonstrated a significant lack of awareness or comfort regarding the recognition and evaluation of patients with PIDDs.⁶⁵

In patients with immune deficiency, PIDDs must be distinguished from secondary immunodeficiency disorders. These latter conditions represent acquired immune defects that occur as either a result of exogenous factors or together with nonimmunologic primary disease processes. They are encountered much more frequently than PIDDs. Causes of secondary immunodeficiency states include infection (e.g., by human immunodeficiency virus [HIV]), medications (e.g., corticosteroids), malnutrition, and neoplastic or metabolic diseases (e.g., Hodgkin disease, diabetes mellitus, cystic fibrosis, and systemic lupus erythematosus [SLE]). These factors may also affect a fetus in utero and present in the neonatal period. Thus they must be considered in infants who exhibit signs or symptoms of immune deficiency.

An immunologic evaluation is indicated when a patient develops unusually frequent or severe infections or when infections are caused by atypical or pathognomonic organisms (Box 67.1). Most of these individuals are immunocompetent and have risk factors for increased frequency of infections, such as allergic disorders, anatomic abnormalities (e.g., eustachian tube dysfunction), or increased exposure to pathogens (e.g., attendance at daycare). They may also have a clinical condition that results in an acquired immunodeficiency state. However a number of children will have an established PIDD and will benefit from prompt referral to a clinical immunologist for early diagnosis and management.

This chapter will focus on the elements of the medical history and physical examination that suggest a diagnosis of a PIDD. Relevant laboratory tests are discussed. Representative antibody, combined (primarily T- and often B-cell) immunity, complement, phagocytic, and other innate immunity deficiencies are presented. Finally a summary of PIDDs that are known to be associated with susceptibility to certain infectious pathogens is provided.

INITIAL EVALUATION FOR SUSPECTED IMMUNODEFICIENCY

Medical History

A comprehensive medical history remains essential for identifying children with a defective immune response. Children with PIDDs often have a history of frequent or severe infections (e.g., pneumonia, meningitis, septicemia, osteomyelitis, abscesses of soft tissue or an internal organ). Although infections occur routinely throughout childhood, epidemiologic studies have established a range for the average number of infections that a normal child may develop per year. For example, otherwise healthy children younger than 5 years of age average between

three and eight episodes of upper respiratory tract infections annually.^{56,73,76} By 1 year of age, 62% of children have had at least one acute otitis media infection, and 17% have had three or more episodes.¹⁴⁵ By 3 years of age, more than 80% of children have had at least one episode of acute otitis media, and 46% have had three or more episodes. The incidence of gastroenteritis among children in the United States is approximately two to three episodes per child-year, with rates as high as five episodes per child-year among children attending daycare centers.^{12,59} The frequency of these infections in normal children during infancy or early childhood can be modified by several factors, including immunologic immaturity or naïveté (i.e., lack of prior exposure to infectious agents), poor hygiene, mouthing behavior, allergic disease, exposure to tobacco smoke, and frequent exposure to ill contacts in the home, school, or daycare settings.

Other elements of the infection history may raise concern for the presence of a PIDD. Clinicians should suspect immune deficiency when the course of an infection is unusually prolonged or associated with unexpected complications (e.g., lung abscess in a child with pneumonia or osteomyelitis as a complication of sinusitis). In general, infections of multiple body sites over time more highly suggest a defective immune response than infections occurring at only one site (e.g., recurrent otitis media alone). In the latter circumstance, a mechanical or anatomic etiology (e.g., foreign body, occult tracheoesophageal fistula in a child with recurrent pneumonia, allergic inflammation, congenital fistulous tract to the middle ear in a child with recurrent bacterial meningitis) should be considered.

Identified infectious organisms may themselves suggest a defect in a particular compartment of the immune system. Several pathogens are discussed in depth at the end of this chapter. Children with primary antibody deficiencies are typically susceptible to infections caused by polysaccharide-encapsulated extracellular bacteria (e.g., *Streptococcus pneumoniae*, *Haemophilus influenzae*). In contrast, children with T-cell-mediated immune deficiencies often develop infections caused by unusual or opportunistic viruses, fungi, protozoa, and mycobacteria (Table 67.1). Because of impaired T-cell-dependent antibody responses, bacterial infections may also be observed. Children with primary deficiencies of complement proteins can present with a history of recurrent neisserial infections, and patients with certain phagocyte deficiencies may have invasive infections due to catalase-positive bacterial (e.g., *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Serratia marcescens*) or fungal (e.g., *Aspergillus* spp.) organisms.

Other elements of the clinical history may help to define the risk for and nature of a potential PIDD. Because young infants are afforded some protection against infections by the presence of maternal immunoglobulin (Ig) G, children with primary antibody deficiencies generally begin to develop infections between 3 and 18 months of age. In contrast, children with severe T-cell-mediated, complement, or phagocytic deficiencies may have onset of infections in the first days or weeks of life. Omphalitis, resulting in delayed detachment of the umbilical cord stump, and poor wound healing suggest phagocytic deficiency. Hypocalcemic seizures in the neonatal period and congenital heart disease should lead to suspicion for a diagnosis of DiGeorge syndrome. Severe infection from live vaccine strains after immunization (e.g., bacille Calmette-Guérin [BCG] lymphadenitis, measles, poliomyelitis, varicella, rotavirus) warrants screening for functional immunologic defects.

The family history can augment suspicion for the presence of a PIDD. A history of consanguinity, recurrent or unusual infections, or

BOX 67.1 When to Suspect an Immunodeficiency Disorder

- Frequency of infectious illnesses higher than expected
- Unusual severity or duration of infectious disease
- Poor response to conventional antibiotic therapy
- Unusual organisms or opportunistic infections causing disease
- Failure to thrive secondary to frequent illnesses
- Poor wound healing
- Noninflammatory *Staphylococcus* spp. skin infection (or absence of pus)
- Recurrent periodontitis
- Low granulocyte or lymphocyte count

BOX 67.2 X-Linked Primary Immunodeficiency Diseases

- X-linked agammaglobulinemia (Bruton disease)
- Immunodeficiency with hyper-immunoglobulin M (CD40 ligand deficiency)
- X-linked ectodermal dysplasia with immunodeficiency (NEMO deficiency)
- Immunodeficiency, polyendocrinopathy, enteropathy, X linked (IPEX)
- X-linked lymphoproliferative syndrome
- Severe combined immunodeficiency (common γ -chain deficiency)
- Properdin deficiency
- Wiskott-Aldrich syndrome
- X-linked chronic granulomatous disease

TABLE 67.1 Common Pathogens in Children With Primary Immunodeficiency Diseases

Immunodeficiency	Common Pathogens
Antibody deficiencies	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Staphylococcus aureus</i> , <i>Pseudomonas aeruginosa</i> , <i>Mycoplasma</i> , <i>Salmonella</i> , <i>Shigella</i> , <i>Campylobacter</i> , rotavirus, enteroviruses, <i>Giardia</i>
Combined immune deficiencies	Pathogens in antibody deficiencies plus: <i>Mycobacteria</i> , <i>Candida</i> , <i>Pneumocystis jiroveci</i> , herpesviruses, adenoviruses
Complement deficiencies	<i>Neisseria</i> , <i>S. pneumoniae</i> , <i>H. influenzae</i>
Phagocyte deficiencies	<i>S. aureus</i> , <i>B. cepacia</i> , <i>Nocardia</i> spp., <i>Serratia</i> , <i>Klebsiella</i> , enteric gram-negative bacilli, <i>Aspergillus</i> , <i>P. aeruginosa</i>

deaths from infection or from unexplained causes during infancy or early childhood in close relatives increases the likelihood for an inheritable immunologic defect. Many PIDDs have X-linked inheritance patterns (Box 67.2), explaining the male-to-female ratio of 5:1 observed in children with PIDDs.

Physical Examination

In patients who are very young and have not been exposed to requisite pathogens to develop infections, the physical examination in many children with PIDDs often provides few clues pointing to an immune defect. A paucity of lymphoid tissues (e.g., tonsils, lymph nodes) may suggest impaired lymphocyte development at an early age. Other examples of helpful physical stigmata include the characteristic facial features (Fig. 67.1) and cardiac malformations in children with DiGeorge syndrome.

In older children, physical examination findings may help to increase suspicion for the presence of a PIDD. Short stature with wasting or

FIG. 67.1 Typical facial appearance of a child with DiGeorge syndrome. Notice the microstomia, hypertelorism, upturned nose, and posteriorly rotated and small, low-set ears.

FIG. 67.2 Telangiectasias of the bulbar conjunctivae in a child with ataxia-telangiectasia.

failure to thrive appear frequently, likely due to recurrent infections or other chronic issues, such as intestinal malabsorption associated with persistent or frequent diarrhea. Recurrent or recalcitrant oral candidiasis, omphalitis, or multiple skin abscesses can serve as signs of immune deficiency. Severe rash, hepatomegaly, and lymphadenopathy are observed in conditions such as Omenn syndrome. Telangiectasias of the bulbar conjunctivae (Fig. 67.2), nasal bridge, ears, and flexor surfaces of the extremities, with or without ataxia, suggest a diagnosis of ataxia-telangiectasia. Chronic eczema can be observed in the hyperimmunoglobulinemia E (hyper-IgE) and Wiskott-Aldrich syndromes, and severe gingivitis with secondary loss of alveolar bone and dentition (Fig. 67.3) can occur in children with leukocyte adhesion deficiency (LAD).

FIG. 67.3 (A) Chronic periodontitis in a boy with leukocyte adhesion deficiency. (B) Radiograph of the same patient shows extensive alveolar bone loss. (Courtesy Dr. Bruce Carter, Texas Children's Hospital, Houston, TX.)

TABLE 67.2 Screening Tests for Suspected Primary Immunodeficiency Disease

Immunodeficiency	Screening Tests
All types	Complete blood cell count Peripheral blood smear
Antibody deficiency	Quantitative serum immunoglobulins: IgG, IgA, IgM, IgE Postimmunization specific IgG antibody titers Isohemagglutinins
T-cell deficiency	Delayed hypersensitivity skin tests or lymphocyte proliferation response to mitogens Chest imaging studies for thymus size Lymphocyte subset phenotyping
Complement deficiency	Total hemolytic complement (CH50) assay
Phagocyte deficiency	Dihydrorhodamine (DHR)-1,2,3 reduction by flow cytometry Neutrophil CD18 and CD15 expression

Laboratory Tests

Widely available, relatively inexpensive laboratory tests can be used to screen for the presence of a PID and exclude most of the severe disorders (Table 67.2). The evaluation should be targeted to the type of immune deficiency (e.g., antibody deficiency vs. phagocyte deficiency) suspected by the medical history and physical examination findings. Laboratory test results must be interpreted against age-defined ranges because normal absolute lymphocyte counts, serum immunoglobulin levels, T-cell counts, and other immune parameters change physiologically with age.¹⁰⁹ Tests to exclude secondary immune deficiency caused by HIV infection, malnutrition, or metabolic disorders should always be considered.

A complete blood count with manual differential provides an excellent screening test for PIDs. Because 50% to 70% of circulating lymphocytes consist of T cells, children with defects in T-cell production (e.g., severe combined immunodeficiency [SCID], complete DiGeorge syndrome) can typically be recognized by absolute lymphopenia. Meanwhile children with Wiskott-Aldrich syndrome are characterized by reduced numbers of platelets that are small (decreased mean platelet volume), a feature that is specific for this syndrome and the related X-linked thrombocytopenia. Large neutrophil cytoplasmic granules are observed in children with Chédiak-Higashi syndrome. Furthermore a complete blood cell count can help to exclude congenital neutropenia. Children with LAD, on the other hand, typically exhibit markedly increased baseline neutrophil and total white blood cell counts. The presence of Howell-Jolly

bodies, with or without thrombocytosis, suggests anatomic or functional asplenia.

Evaluation of Humoral Immunity

Screening assessments for antibody deficiency should include quantitative measurement of serum immunoglobulin levels and functional assessment of specific antibody responses. Evaluations of serum IgG, IgA, IgM, and IgE levels help to identify children with panhypogammaglobulinemia, IgA deficiency, hyper-IgM syndrome, hyper-IgE syndrome, and so forth. Functional antibody production should be tested by measuring antibody titers generated in response to immunization with vaccines, such as *Diphtheria* and tetanus toxoids. Antibody responses to polysaccharide antigens should be assessed separately using the 23-serotype pneumococcal polysaccharide vaccine after 24 months of age.¹¹¹ Infants younger than 2 years are felt to have functional immaturity in the ability to respond to this class of antigens, although this assertion has been challenged.^{10,86} Alternatively, because ABO blood group antigens are polysaccharides, and cross-reacting environmental antigen epitopes exist ubiquitously, some antipolysaccharide antibody production may be assessed by measuring serum isohemagglutinin titers, taking into consideration the fact that children with blood type AB do not form isohemagglutinins. The 13-valent conjugated pneumococcal antigen and *H. influenzae* type b vaccines do not assess antipolysaccharide antibody responses because the immune response to the conjugated protein element drives antibody production to each target antigen. Patients vaccinated with the conjugated pneumococcal vaccine can still be evaluated for antipolysaccharide antibody production to the serotype antigens in the pneumococcal polysaccharide vaccine that are not present in the conjugated vaccine, however. Assessments of children whose screening tests indicate significant humoral immune abnormalities should be followed by enumeration of B-cell subsets in the peripheral blood.

Evaluation of T-Cell–Mediated Immunity

The screening evaluation for T-cell deficiency can begin without specialized immunologic testing. Assessments include measurement of the absolute lymphocyte count, delayed hypersensitivity skin tests, and, in the young infant, posteroanterior and lateral chest radiographs to assess the size of the thymus (Fig. 67.4).

Delayed hypersensitivity skin tests are performed using vaccine or microbial antigens to which the child has had prior exposure. Commonly used antigens include tetanus toxoid and *Candida albicans*. The standard initial dilution is 1:100 for both antigens, but a *C. albicans* dilution of 1:10 may be more appropriate for children 5 years of age or younger who are less likely to have had repeated exposures to this antigen. The diluted antigen is administered intradermally, and the skin reaction is examined for the presence of wheal formation after 24 and 48 hours.

FIG. 67.4 Lateral chest radiograph of an infant with severe combined immunodeficiency disease. Note the absence of the normal thymic shadow.

Specialized tests include enumeration of peripheral blood T cells, T-cell subset phenotyping (e.g., CD4⁺ or CD8⁺ T-cell counts), and mitogen- and antigen-induced lymphocyte proliferation studies.¹⁰⁹

Evaluation of the Complement System

Deficiencies of components of the classic complement pathway can be detected by the total serum hemolytic complement (CH50) assay. This test measures the ability of complement proteins in fresh patient serum to lyse antibody-coated sheep erythrocytes and reflects the activity of all components of the classic complement pathway from C1 through C9. Complete deficiency of any of these components results in very low CH50 values. Improper sample handling can produce low CH50 results. Thus assessments of single complement component levels and targeted functional testing should only be pursued when the CH50 value is zero or near zero.¹⁶⁴ Measurement of serum levels of C3 and C4 is available in most clinical laboratories. The alternate complement pathway is assessed with a similar assay (AH50).

Evaluation of Phagocyte Function

Few assays are available for the assessment of phagocyte function. Children with chronic granulomatous disease (CGD) show abnormally reduced superoxide production in phagocytes in a flow cytometry analysis that detects using dihydrorhodamine-1,2,3 (DHR) as a fluorescent indicator.¹⁰⁹ More sophisticated tests available in research laboratories include assays of chemotaxis, phagocytosis, and bactericidal activity, which may be performed when a high clinical suspicion of a phagocytic disorder exists. Assessment of CD18 and CD15 expression on white blood cells is indicated when a diagnosis of LAD is suspected.

Genetic Testing

More than 300 molecular defects have been identified as causes of PIDDs (Table 67.3). Gene sequence testing for many of these defects is available in a few specialized laboratories and should be pursued when a PIDD with a known genetic defect is suspected.¹⁷¹ In patients for whom a PIDD is highly likely, and the clinical phenotype can be caused by a defect in one of several candidate genes, whole exome or genome sequencing may be considered.^{167,172} Genetic testing is recommended for patients who have a suspicious clinical history and abnormal immune function, for prenatal diagnosis of an unborn child who has a sibling with a known PIDD, and for an individual who may have inherited or who may be a carrier of a known PIDD gene defect. For some conditions, identification of the specific genetic defect may help to determine prognosis and therapeutic options. For example, it has been established that patients with SCID due to Artemis deficiency should not be given

TABLE 67.3 Examples of Gene Defects in Primary Immunodeficiencies

Immunodeficiency	Defect	Chromosome
Antibody Deficiency		
Agammaglobulinemia	Heavy-chain immunoglobulin	14q23
	Bruton tyrosine kinase	Xq22
Hyper-IgM syndrome	Activation-induced deaminase	12p13
	CD40 ligand (<i>CD40LG</i>)	Xq26
Cellular Immunodeficiency		
DiGeorge syndrome	Unknown	22q11.2, 10p13
Severe combined immunodeficiency disease	<i>RAG1</i> , <i>RAG2</i>	11p13
	<i>JAK3</i>	19p13.1
	Adenosine deaminase	20q13.11
	Common γ -chain	Xq13.1
	IL-7 receptor- α	5p13

Leukocyte adhesion deficiency type I	<i>ITGB2</i>	21q22

alkylator therapy during conditioning for hematopoietic stem cell transplantation because use of such agents is associated with poor growth, abnormal dental development, and late endocrinopathies after transplantation.¹³⁰ Determination of the specific genetic defect is also necessary for genetic counseling, usually regarding the probability that the parents will have another child with the same condition.

Neonatal Screening for T-Cell Deficiencies

In June 2010, the U.S. Department of Health and Human Services approved the addition of SCID to the list of diseases recommended for universal neonatal screening.¹³³ Children with severe T-cell deficiencies, such as SCID, are born with absent or very low numbers of T-cell receptor excision circles (TRECs), which are DNA byproducts of T-cell receptor recombination. In 2005, Drs. Puck and Chan demonstrated that TREC levels can be measured using blood spots from Guthrie cards.²⁹ Newborn screening for SCID was subsequently pioneered in Wisconsin in 2008 and continues to be rapidly implemented across the nation. As of July 2017, 44 states and the District of Columbia had active programs to screen all newborns for SCID, resulting in the testing of more than 10 million infants.¹⁷⁰ An additional four states committed to begin screening before the end of 2017. The programs have shown notable success in identifying children with SCID and other PIDDs, resulting in excellent treatment outcomes.⁸⁰ Thus all infants who have abnormal newborn screening results for SCID should be evaluated by a clinical immunologist according to the specific algorithm developed by the Health Department of that state. Newborn screening has also determined that the incidence of SCID in the United States is one per 58,000 live births. A similar approach for the diagnosis of B-cell deficiencies in the newborn is being developed.¹⁵

Management

The immunodeficient patient requires specialized care according to the specific diagnosis and clinical condition. For example, hematopoietic stem cell transplantation is indicated for many PIDDs and needs careful individualized assessment of risks and benefits to provide a treatment protocol that ensures optimal outcomes.^{24,115}

BOX 67.3 Key Concepts in the Management of Primary Immunodeficiencies

Immune function: T- and B-cell number and function should be assessed periodically.

IgG replacement therapy: Infusions are indicated for patients with poor antibody responses to immunizations.

Immunizations: Live vaccines should not be administered to patients who have severe T-cell deficiencies unless they have received definitive treatment. Household contacts of children with immunodeficiency should not receive oral poliovirus vaccines because of the risk for transmission to the immunodeficient child. Other live vaccines (BCG, MMRV) may be administered to household contacts. If the vaccine recipient develops a rash, contact with the immunodeficient child should be avoided.⁷

Blood products: When needed, patients with immune deficiencies should receive only irradiated, cytomegalovirus-negative, leukocyte-depleted blood products.

Antibiotic prophylaxis: T-cell–deficient patients should be given antibiotic prophylaxis to prevent *Pneumocystis jirovecii* infection. Antibiotic prophylaxis is recommended for dental and surgical procedures and should be considered for patients with recurrent infections.

Infectious diseases: Infections should be recognized promptly, and unusual pathogens should be considered. Antibiotic therapy should be started early and discontinued cautiously.

Diet and activity: Patients with immune deficiency should have a regular diet and lifestyle but should be instructed to avoid eating raw food and playing in environments potentially highly contaminated with pathogens, including daycare centers. Strict hand-washing precautions and reverse isolation may be indicated for patients with poor T-cell function.

Administration of intravenous or subcutaneous IgG (IVIG or SCIG, respectively) serves as a common therapeutic measure for patients who lack IgG antibody responses, whether isolated or as part of combined immune deficiency.¹⁷³ Other recommendations specific to patients with PIDDs may include exclusion from contact with infectious illness and avoidance of live vaccines^{6,135}; use of irradiated, leukocyte-depleted, cytomegalovirus-negative blood products when needed; antibiotic prophylaxis; and prompt diagnosis and treatment of infections. Aside from patients with severe T-cell deficiency awaiting hematopoietic stem cell transplantation, isolation in sterile environments is not recommended because the risk for infection must be balanced with the severe impact in psychosocial development induced by isolation. Instead the infection risk should be minimized using advances in the treatment and prevention of community-acquired infections (Box 67.3).

SELECTED PRIMARY ANTIBODY DEFICIENCIES**X-Linked Agammaglobulinemia****Clinical Features**

Boys with X-linked agammaglobulinemia (XLA) are often healthy during the first months of life due to the protective presence of transplacentally acquired maternal IgG. As maternal immunoglobulin disappears from the infant, chronic or recurrent infections develop.^{36,37,119,165} The most common findings include recurrent otitis media, sinusitis, pneumonia, and diarrhea, but infections are not limited to mucosal surfaces: bacteremia, meningitis, and osteomyelitis may also occur. In a retrospective study of 201 patients with XLA, the mean age at diagnosis was 2.5 years in patients with a family history of the disease and 3.5 years when no family history was present.¹⁶⁵ The most common bacterial pathogens identified in patients with XLA include *S. pneumoniae*, *H. influenzae*, *S. aureus*, and *P. aeruginosa*. *Mycoplasma* spp. infections also occur with increased frequency and have been implicated as a cause of a subacute, destructive arthritis. Gastrointestinal infections may be caused by *Salmonella*, *Shigella*, *Campylobacter*, or rotavirus. Chronic giardiasis with intestinal malabsorption has been observed. Patients with XLA

also demonstrate increased risk for enteroviral infections, particularly viral meningoencephalitis.

Pathogenesis

The defective gene (*BTK*) maps to the midportion of the long arm of the X chromosome. The gene encodes a cytoplasmic tyrosine kinase, BTK, which is a signal transducer necessary for B-cell survival during maturation.¹⁴⁹ As a consequence, blood, lymph nodes, and bone marrow contain markedly diminished numbers of B cells and plasma cells, resulting in agammaglobulinemia. BTK also plays a role in viral immunity within macrophages and dendritic cells, perhaps explaining the enteroviral susceptibility.^{81,82,90,138}

Diagnosis

Because of the presence of transplacentally acquired maternal IgG, a normal level of serum IgG in a male infant during the first 6 months of life does not exclude the diagnosis of XLA. IgA, IgM, and IgE levels may be low as well, but defining values that clearly differentiate infants with the disease from normal infants has remained difficult. Diagnosis can be better obtained by immunophenotyping, using flow cytometry analysis to demonstrate absence of B cells in peripheral blood. After an infant with XLA reaches 6 months of age, serum IgG concentrations usually fall below 100 mg/dL, and levels of other immunoglobulin isotypes remain low or undetectable. No isohemagglutinins are present, and specific antibodies are not produced in response to immunization or natural infection. Recurrent infections or early mortality in male family members may suggest the characteristic X-linked pattern of inheritance. Definitive diagnosis is obtained by identifying functionally deleterious mutations in the *BTK* gene.

Treatment and Prognosis

Lifetime IgG replacement therapy is needed for all patients with XLA.¹¹³ It decreases the frequency of severe infections, reduces the need for hospitalization, and helps to prevent the development of chronic lung disease with progressive decline in pulmonary function. The dose and frequency of administration of IVIG or SCIG should be adjusted to minimize the frequency of infections. Some patients receiving IVIG will require serum IgG trough levels of 800 to 1300 mg/dL to achieve this goal.⁹¹ Most patients receive IVIG at a dose of 400 to 600 mg/kg every 3 or 4 weeks or SCIG at 140 to 200 mg/kg weekly. Patients who are given SCIG should have steady-state serum IgG levels measured periodically (SCIG administration does not produce trough serum IgG levels). SCIG recipients should maintain steady state serum IgG levels higher than the serum IgG trough level targeted by IVIG administration in order to achieve a comparable pharmacokinetic area under the curve.

Infections should be treated aggressively in patients with XLA. Routine middle ear, sinus, and skin infections usually respond to oral antibiotics. Therapy for pneumonia and other significant focal or systemic infections should start with intravenously administered antibiotics. Empirical antibiotic therapy should be directed against common bacterial pathogens, including *S. pneumoniae*, *H. influenzae*, and *S. aureus*. If possible, a causative pathogen should be identified, particularly in severe or chronic infections. Additional doses of IVIG are indicated for treatment of pneumonia or invasive infections. Because chronic pulmonary disease with bronchiectasis represents a significant cause of mortality in patients with XLA, defined periods of antibiotic therapy, similar to strategies employed in patients with cystic fibrosis, may be helpful for certain patients.

Immunoglobulin Deficiency With Increased IgM**Clinical Features**

About 70% of patients with immunoglobulin deficiency with increased IgM (i.e., hyper-IgM syndrome) are male, associated with X-linked inheritance of the condition, while the remainder display an autosomal recessive inheritance pattern.^{8,83,85,103,120} Patients with this disorder develop recurrent pyogenic infections during infancy as transplacentally acquired maternal IgG wanes. Recurrent respiratory tract infections and chronic diarrhea with failure to thrive occur; patients can develop septicemia, meningitis, and other invasive infections as well. Patients who have hyper-IgM syndrome due to defects in the CD40 and NF-κB signaling

FIG. 67.5 Conical teeth characteristic of immunodeficiency due to defects in the *IKBKG* gene (NEMO deficiency).

pathways carry increased risk for opportunistic infections, such as *Pneumocystis jiroveci* pneumonia.¹²⁰

Other clinical manifestations can also arise. Almost two-thirds of patients with hyper-IgM syndrome have a history of neutropenia, which typically appears intermittently but without the precise periodicity of cyclic neutropenia.¹²⁰ Patients frequently develop aphthous ulcers; perirectal ulcers and abscesses have also been reported. Lymphoid hyperplasia can develop in patients who have defects in enzymes responsible for isotype switching and somatic hypermutation. Intestinal nodular lymphoid hyperplasia may lead to malabsorption and protein-losing enteropathy. Patients also demonstrate increased risk for malignancy and autoimmune disease, including arthritis and nephritis, compared to normal children. Male patients with mutations in *IKBKG* may but do not necessarily have anhidrotic ectodermal dysplasia and conical teeth (Fig. 67.5).

Pathogenesis

Several genetic defects have been identified as causes of hyper-IgM syndrome. Most boys with hyper-IgM syndrome have mutations in *CD40LG*, a gene on the X chromosome that encodes the T-cell ligand for CD40.^{3,8} CD40 is a signaling molecule that is expressed on the surface of B cells; several patients with hyper-IgM syndrome due to CD40 deficiency have also been reported.¹²⁰ Engagement of CD40 by CD40 ligand is essential for B-cell proliferation, isotype switching, and terminal differentiation into antibody-secreting plasma cells. Most cases of autosomal recessive hyper-IgM syndrome occur due to mutations in the activation-induced cytidine deaminase (*AICDA*) and the uracil DNA glycosylase (*UNG*) genes.^{103,120} Hyper-IgM syndrome can also be caused by defects in NEMO, encoded by *IKBKG* on the X chromosome,^{137,169} and *IKBα*, which both play key roles in modulation of NF-κB signaling.¹²⁰ Most mutations in *IKBKG* are lethal for male fetuses, and female carriers of these mutations may have incontinentia pigmenti.

Diagnosis

Various laboratory test findings can help to establish the diagnosis. Most patients with hyper-IgM syndrome have a characteristic increase in serum IgM level with low to absent concentrations of serum IgA and IgG. Serum IgM concentrations may exceed 1000 mg/dL. However, they can also exist within the normal range, especially in younger children. Patients have normal numbers of circulating IgM⁺ B cells but few B cells that express surface IgA or IgG. Antibody responses to immunization may be present but consist predominantly or exclusively of IgM antibodies because isotype switching does not occur. Evaluation of boys with suspected hyper-IgM syndrome should include assessment of CD40 ligand expression in activated T cells by flow cytometry and genetic sequencing of *CD40LG*.⁸

BOX 67.4 Criteria for the Diagnosis of Common Variable Immunodeficiency Disease

- At least one of the following:
 - Increased susceptibility to infection
 - Autoimmune manifestations
 - Granulomatous disease
 - Unexplained polyclonal lymphoproliferation
 - Affected family member with antibody deficiency
- And marked decrease of IgG and marked decrease of IgA with or without low IgM levels (measured at least twice; <2 standard deviations below the normal levels for age)
- And at least one of the following:
 - Poor antibody response to vaccines (and/or absent isohemagglutinins)
 - Low switched-memory B cells (<70% of the age-related normal value)
- And secondary causes of hypogammaglobulinemia have been excluded
- And diagnosis is established after the fourth year of life (although symptoms may present before that age)
- And no evidence of severe T-cell deficiency, defined as two of the following:
 - CD4⁺ cells/mm³: 2–6 years old, <300; 6–12 years old, <250; >12 years, <200
 - Naive CD4⁺ %: 2–6 years old, <25; 6–16 years old, <20; >16 years, <10
 - Significantly decreased T-cell proliferation to stimulation

Ig, Immunoglobulin.

Treatment and Prognosis

Patients with hyper-IgM syndrome must be followed closely. All affected individuals require IgG replacement therapy.¹¹³ Patients with defects in the CD40 and NF-κB signaling pathways should receive antibiotic prophylaxes against a limited number of opportunistic pathogens, such as *Pneumocystis* or atypical mycobacteria, as well. Males with *CD40LG* defects have increased morbidity and mortality compared with patients with autosomal forms of hyper-IgM syndrome, likely related to the fact that *CD40LG* deficiency affects both T and B cells. Significant causes of long-term mortality include invasive infections, liver failure, and malignancy.¹²⁰ Hepatic diseases include sclerosing cholangitis, cirrhosis, and hepatocellular carcinoma and are associated with *Cryptosporidium parvum* infection.¹²⁰ Thus patients should be warned against trips to water parks and drinking of tap water. Human leukocyte antigen (HLA)-identical bone marrow transplantation has been successful in treating this condition and should be considered early after diagnosis before severe complications occur. Administration of recombinant CD40 ligand or agonistic anti-CD40 antibodies has also been reported to improve immune responses in these patients.^{49,69}

Common Variable Immunodeficiency Disease

Clinical Features

Common variable immunodeficiency disease (CVID) includes a heterogeneous group of antibody-deficient disorders with similar clinical manifestations, such as recurrent infections and a propensity for autoimmune conditions.¹⁴ Although the diagnosis is often given indiscriminately, CVID is strictly defined using diagnostic criteria established by the European Society for Immunodeficiencies (Box 67.4).⁵ Onset can occur at any age. A study of more than 2200 European patients with CVID has demonstrated two peaks for diagnosis: during childhood and between 30 and 40 years of age.⁵²

CVID typically manifests with susceptibility to infections in a similar manner to XLA and hyper-IgM syndrome.¹⁰⁸ Patients develop recurrent bacterial infections of the respiratory tract or invasive bacterial infections. Bronchiectasis and chronic lung disease from recurrent pneumonias remain significant causes of long-term morbidity and mortality.⁵² The most common infectious organisms isolated from the respiratory tract include *S. pneumoniae* and *H. influenzae*.¹⁰⁸ Many individuals with CVID

develop chronic diarrhea and intestinal malabsorption associated with gastrointestinal infections by *Giardia*, *Campylobacter*, and *Salmonella*.¹⁰⁸ The inflammation induced by these infections can result in protein-losing enteropathy, which may exacerbate the underlying hypogammaglobulinemia. Patients are also susceptible to infections of the genitourinary tract, joint tissues, and lungs by *Ureaplasma* spp.¹⁴

Patients with CVID can demonstrate increased risk for noninfectious complications.^{14,52} They are known to have increased prevalence for ulcerative colitis, Crohn disease, other enteropathies, atrophic gastritis with achlorhydria, and cholelithiasis. Almost 30% of individuals with CVID develop autoimmunity, which includes chronic arthritis resembling rheumatoid arthritis, scleroderma, lupus-like disease, hypothyroidism, autoimmune chronic hepatitis, and autoimmune cytopenias.⁵² Abnormal lymphoid proliferation, granulomas, and malignancies, such as lymphoma and gastric carcinoma, appear over time in some patients. They can develop a pseudolymphoma syndrome in the lungs (i.e., lymphoid interstitial pneumonia) and intestines (i.e., nodular lymphoid hyperplasia), splenomegaly, or mediastinal adenopathy.⁵²

Pathogenesis

No single genetic defect has been widely identified as the cause of CVID. Instead the diagnosis of CVID encompasses a number of different genetic defects that result in loss of antibody secretion.¹¹² B-cell phenotyping studies have demonstrated a variety of maturational defects in patients with CVID.⁴⁴ Decreased or absent numbers of switched memory B cells is associated with disease severity and development of autoimmune disorders and malignancies.^{2,125,163} A variety of T-cell functional abnormalities also have been reported. They include decreased lymphocyte proliferation to mitogens and antigens and reduced expression of cytokines. Overall, polymorphisms or mutations in the *TNFRSF13B*, *ICOS*, *MSH5*, *TNFRSF13C*, *CD27*, *CD81*, *CD19*, *MS4A1*, *CR2*, *NFKB2*, and *LRBA* genes have all been individually associated with disease in several families or individuals with CVID.^{14,28,32,78,89,131,153,154,160}

Diagnosis

The diagnosis should be established according to defined criteria (see Box 67.4).⁵ The clinical history must support a diagnosis of CVID. In terms of laboratory studies, the serum IgG and IgA levels must be less than 2 standard deviations below the normal ranges for age, and patients with CVID will typically have a serum IgG level persistently below 250 to 300 mg/dL. Patients must also demonstrate either impaired antibody responses to immunizations or low numbers of switched memory B cells; some patients will have both abnormalities. Secondary causes of hypogammaglobulinemia and severe T-cell deficiency must be excluded. The diagnosis of CVID is not generally given to patients under 4 years of age.

Treatment and Prognosis

No therapies are currently recommended for definitive treatment of CVID. Hematopoietic stem cell transplantation has been demonstrated to result in survival of less than 50%.¹⁶² Thus patients must be given lifelong IgG replacement therapy to minimize the frequency of infections, particularly of the lungs.¹¹³ Some patients require IVIG doses to maintain serum IgG trough levels of 500 to 1700 mg/dL or SCIG doses to achieve pharmacokinetically equivalent levels of steady-state serum IgG in order to accomplish this goal.^{52,91} Patients with CVID who have enteric protein loss due to enteropathy may require remarkable doses of IVIG or SCIG to maintain protective serum IgG concentrations. Limited antibiotic prophylaxis may be needed as an adjunctive measure in patients who continue to develop infections, especially in sites primarily protected by secretory IgA (e.g., the sinuses), despite appropriate serum IgG levels. Patients who have low serum IgM levels carry significantly increased risk for developing bronchiectasis.⁵² Overall, however, morbidity and mortality in patients with CVID are equally associated with either infectious (e.g., chronic lung disease with bronchiectasis) or noninfectious (e.g., autoimmunity, lymphoid hyperplasia) complications.⁵²

IgA Deficiency

Clinical Features

IgA deficiency is the most common PIDD. Its prevalence varies by ethnicity but ranges from one in 155 individuals to one of every 18,550.¹⁵⁹

In Caucasians, it appears at a frequency of one in 300 to one in 1200 persons.¹³⁶ The vast majority of individuals with IgA deficiency are clinically asymptomatic.^{136,159} Some patients develop recurrent infections of the respiratory tract, gastrointestinal tract (e.g., by *Giardia*), or other tissues.⁹² IgA deficiency is associated with increased risk for autoimmunity, such as SLE, rheumatoid arthritis, pernicious anemia, autoimmune thyroid disease, type 1 diabetes, or celiac disease.^{136,159} Lymphoid and gastrointestinal malignancies may occur more frequently than in the general population. An association with increased atopy has been suggested but remains controversial.^{136,159}

Pathogenesis

The pathogenesis of IgA deficiency has not been determined. Of interest, some individuals with selective IgA deficiency subsequently develop CVID, and variations in *TNFRSF13B* and *ICOS* genes have been found in families with members that have either of these conditions.²⁸ Genetic variations within the major histocompatibility complex (MHC) III region on chromosome 6 have also been associated with the development of selective IgA deficiency and CVID, further arguing that these two disorders may be related.¹⁵⁷ In particular, the *MSH5* gene falls within this region, and mutations in this gene have been implicated as a cause of CVID.¹⁵⁹ Certain HLA haplotypes, such as 8.1, undeniably play a role, and associated candidate genes near or within the MHC class II and II regions are being investigated.^{136,159} Mutations in other genes outside of MHC regions have also been proposed as causes of IgA deficiency. Associated genes include *IFIH1*, *CLEC16A*, *TNFAIP3*, *PVT1*, *FAS*, *CDH23*, and *TM7SF3*.^{136,159}

Diagnosis

International consensus defines selective IgA deficiency as the presence of serum IgA levels of less than 7 mg/dL with normal IgG and IgM levels in individuals 4 years of age or older.^{87,136,159} Normal serum IgA concentrations can vary in children under the age of 4 and can even be undetectable in healthy infants younger than 6 to 9 months of age. In fact, more than 20% of children who meet criteria for a diagnosis of IgA deficiency between 4 and 10 years of age no longer have serum IgA levels of less than 7 mg/dL when they become adolescents, arguing that the diagnosis should be given very carefully in the pediatric population.⁸⁷

Treatment and Prognosis

IVIG and SCIG therapies are not indicated for the treatment of patients with selective IgA deficiency. Respiratory tract infections in individuals with selective IgA deficiency may require prolonged courses of antibiotic therapy. Antibiotic prophylaxis for respiratory tract infections should be considered if infections recur frequently. Parenteral antibiotics may be needed for refractory cases of sinusitis or pneumonia. IgA-deficient patients carry a small risk for development of IgE-mediated anaphylaxis if sensitized to IgA and given a blood product that contains IgA.¹²² The incidence of this kind of reaction is estimated to range between one in 20,000 and one in 47,000 transfusions.¹³⁶ Broad, routine restriction of IgA-deficient patients against receiving IgA-containing blood products is not recommended.¹²⁶

Transient Hypogammaglobulinemia of Infancy

Clinical Features

Infants with transient hypogammaglobulinemia of infancy (THI) come to medical attention because of recurrent respiratory tract infections (e.g., otitis media, sinusitis) and serum immunoglobulin levels below laboratory normal ranges. Septicemia, meningitis, skin infections, and other invasive infections very rarely occur.^{114,152}

Pathogenesis

THI is caused by delayed physiologic maturation of immunoglobulin synthesis, resulting in prolongation of the relative hypogammaglobulinemia ("physiologic nadir") observed in most normal infants at 3 to 6 months of age as maternal IgG is cleared from the circulation. No molecular etiology has been identified and confirmed. Patients with THI are able to produce protective specific antibody responses.

Diagnosis

The diagnosis can be made with certainty only in retrospect. More than 80% of children with THI recover to normal immunoglobulin levels by 3 years of age.¹⁵² In some children, however, serum immunoglobulin concentrations may remain low until the children are several years of age.^{114,152} Demonstration of normal specific antibody responses can help to support the diagnosis.

Treatment and Prognosis

Infants with suspected THI should be followed clinically, and serial measurements of serum immunoglobulin levels should be performed. Initial immunoglobulin levels may help to predict which infants will recover more quickly.¹⁵² Some children are eventually diagnosed with CVID, selective IgA deficiency, or another immunodeficiency disease. Because THI is self-limited and specific antibody production is normal, IgG replacement therapy is not indicated. Antibiotic prophylaxis may be considered in selected cases for recurrent respiratory tract infections.

IgG Subclass “Deficiency”

Four subclasses of IgG are known to exist. IgG1 constitutes 60% of total IgG, IgG2 accounts for 25%, and IgG3 and IgG4 are present in smaller quantities (10% and 5%, respectively).²³ Normal ranges of serum levels for each subclass vary by age and must be considered when interpreting clinical laboratory data. The prevalence of IgG subclass deficiency has been reported at between 4.8% and 24% for different patient groups.¹⁴⁰ Although various roles for each subclass have been proposed, the exact function of each subclass is not fully understood in immune processes.²³ Thus the importance of isolated IgG subclass deficiency as a PID remains debatable.

In general, patients gain little benefit from measurements of IgG subclass levels and assignment of a diagnosis of IgG subclass deficiency as part of the initial evaluation for suspected PID. First, the clinical relevance of “low” levels of IgG2, IgG3, or IgG4 remains dubious. Individuals have been reported with complete lack of various subclasses who yet remain entirely asymptomatic.²³ In fact, IgG subclass deficiencies may be present in 1% to 3% of healthy persons.²³ Patients with allergic diseases in particular can have IgG subclass deficiencies yet do not merit a diagnosis of humoral immune deficiency.^{39,107} Thus inappropriate measurements of IgG subclass levels can lead to overdiagnosis or misdiagnosis and improper treatment. Second, the levels of IgG subclasses provide no information about humoral function. Most children with low IgG subclass levels demonstrate normal antibody responses against protein and polysaccharide antigens, indicating normal humoral immune function.²³ The rest may have selective antibody deficiency, a separate diagnosis that remains controversial, or another PID. In either case, testing of responses to vaccines is required, indicating that assessments of specific antibody function and not measurements of IgG subclass levels should be performed in the initial evaluation for suspected PIDs.⁹³ Finally, some patients with IgG subclass deficiencies have other clinically relevant PIDs (most commonly IgA deficiency) that can be identified through routine screening tests of immune function.^{23,79} Measurements of IgG subclass levels play no role in establishing the proper diagnosis in these patients.

Most patients with low IgG subclass levels should be managed with reassurance. Routine bacterial infections should be treated with antibiotics. Limited antibiotic prophylaxes against sinopulmonary tract infections may be offered to some patients. Immunoglobulin replacement therapy is not indicated, except perhaps in abbreviated courses for patients who have abnormally poor antibody responses to immunizations and a demonstrated propensity for frequent or chronic infections.

SELECTED PRIMARY COMBINED IMMUNE DEFICIENCIES

Severe Combined Immunodeficiency Disease

Clinical Features

Most infants with SCID appear completely healthy at birth. Thus infants identified by newborn screening programs may not exhibit any clinical abnormalities other than lack of palpable lymph nodes and tonsils. In

the absence of newborn screening, infants with SCID can typically be recognized during the first few months of life by the appearance of recurrent or severe infections.¹³⁹ These infections include recurrent otitis media or pneumonia and persistent or severe viral infections caused by respiratory syncytial virus, parainfluenza virus, adenovirus, or rhinovirus. Infants with SCID may also develop a severe, disseminated infection from cytomegalovirus, especially if accompanied by very high plasma viral load and hemolytic anemia. Infections occur from attenuated virus strains in immunizations, including disseminated varicella after varicella or measles-mumps-rubella-varicella (MMRV) vaccine administration and persistent infection with vaccine strains of rotavirus, oral poliovirus, rubella, or measles virus. Infants with SCID can also develop disseminated infection with BCG after BCG immunization. Other signs of SCID include recurrent or recalcitrant oral and cutaneous candidiasis, septicemia, and other invasive bacterial infections. Patients demonstrate increased susceptibility to routine pathogens (e.g., *S. pneumoniae*, *H. influenzae*), unusual organisms, and opportunistic pathogens, such as *P. jiroveci*. Other signs of SCID include chronic diarrhea and failure to thrive associated with onset of infections. In the neonatal period, a rash may appear that is produced by a graft-versus-host reaction induced by maternal T lymphocytes.

Pathogenesis

SCID represents a heterogeneous group of genetic disorders that share the ability to produce profound failure of both T and B cell function. At least 16 molecular defects have been confirmed to cause SCID (Table 67.4).¹⁷ In the United States, the most prevalent cause of SCID is a defect in the γ chain of the IL-2 receptor, identified in 36% of patients with SCID.¹¹⁵ Because the molecule is encoded by the *IL2RG* gene on the X chromosome, all of these patients are male, and the defect is inherited in an X-linked recessive pattern. This protein is a functional component of the receptors for IL-2, IL-4, IL-7, IL-9, IL-15,

TABLE 67.4 Types of Severe Combined Immunodeficiency

Type	Defect
<i>IL2RG</i> (common γ -chain) deficiency	Signaling for IL-2, IL-4, IL-7, IL-15, and IL-21
<i>JAK3</i> (janus kinase 3) deficiency	Cytokine signaling
<i>IL7R</i> (IL-7 receptor- α) deficiency	Signaling for IL-7
<i>PTPRC</i> (CD45) deficiency	Protein tyrosine phosphatase regulation of signaling, cell activation
<i>CD3D</i> (CD3 δ) deficiency	T-cell receptor signaling
<i>CD3E</i> (CD3 ϵ) deficiency	T-cell receptor signaling
<i>CD247</i> (CD3 ζ) deficiency	T-cell receptor signaling
<i>CORO1A</i> (coronin 1A) deficiency	Defective thymic egress of T cells and T-cell actin organization, homeostasis
<i>RAG1</i> (recombinase activating gene 1) deficiency	Rearrangement of B- and T-cell receptor genes
<i>RAG2</i> (recombinase activating gene 2) deficiency	Rearrangement of B- and T-cell receptor genes
<i>DCLRE1C</i> (Artemis) deficiency	Rearrangement of B- and T-cell receptor genes
<i>PRKDC</i> (DNA PK $_{cs}$) deficiency	Rearrangement of B- and T-cell receptor genes
<i>LIG4</i> (DNA ligase 4) deficiency	Rearrangement of B- and T-cell receptor genes
<i>NHEJ1</i> (Cernunnos) deficiency	Rearrangement of B- and T-cell receptor genes
<i>AK2</i> deficiency (reticular dysgenesis)	Defective stem cell maturation
<i>ADA</i> (adenosine deaminase) deficiency	Metabolite (dATP) toxicity to lymphocytes

and IL-21 and is essential for development of human T cells and natural killer cells.^{74,75} All of the other known causes of SCID are inherited in an autosomal recessive pattern. IL-7 receptor α -chain deficiency produces the second most common cause of SCID in the United States and is followed in frequency by defects in recombinase activating genes 1 and 2 (RAG1 and RAG2), adenosine deaminase (ADA) deficiency, Janus kinase 3 (JAK3) deficiency, and Artemis deficiency.¹¹⁵ In more than 30% of patients, the molecular cause remains unknown.¹¹⁵

Diagnosis

Specific criteria have been established to define the diagnosis of SCID. These requirements include (1) absence or very low number of T cells (less than 300 CD3⁺ T cells/mm³) and no or very low T-cell function (<10% of lower limit of normal) as measured by response to phytohemagglutinin or (2) presence of T cells of maternal origin.¹³⁴

Other studies can help to support the diagnosis of SCID. In states that have newborn screening programs for SCID, very low levels of TRECs may suggest the diagnosis. Clinically, infants with SCID typically lack radiographic evidence of a thymus gland. They usually have absolute lymphocyte counts of less than 2000 cells/mm³.²⁵ Some patients have panhypogammaglobulinemia, whereas others have depressed concentrations of only one or two immunoglobulin isotypes. Antibody responses are profoundly impaired or absent, and delayed type hypersensitivity skin test anergy is observed. X-linked or JAK3-deficient SCID may be suspected if B cells (that do not function) account for all circulating lymphocytes. Biochemical tests for adenosine deaminase and purine nucleoside phosphorylase levels and enzymatic activities are available in specialized laboratories. Testing for a specific genetic defect should be pursued, and a genetic evaluation of immediate relatives for carrier status is recommended for genetic counseling purposes. Lymphocyte enumeration and genetic testing remain especially important for identifying radiosensitive B cell–negative, natural killer (NK) cell–positive forms of SCID.

Treatment and Prognosis

In patients with SCID who have not received definitive therapy, infection risks must be minimized. Infants should be kept isolated from infected individuals as much as possible and kept in reverse isolation with respiratory and contact precautions in hospital settings. Patients with SCID should receive prophylaxis against *Pneumocystis jirovecii* and immunoglobulin replacement therapy. Candidal prophylaxis may be considered as well. Except for live polio virus (no longer available in the United States), all household members should be kept immunized, but the patient should not receive any live viral or bacterial immunizations.¹¹⁷ Any acute infections must be treated aggressively, and providers should set a low threshold for hospital admission. If transfusion of blood products is needed, they must be leukocyte-reduced, irradiated, and CMV negative. Patients with radiosensitive forms of SCID should minimize exposure to sunlight, ultraviolet light, and ionizing radiation, such as γ -radiation delivered during radiologic studies. In addition, providers who perform hematopoietic stem cell transplantation must be made aware of increased sensitivity of tissues to DNA crosslinking medications and adjust any conditioning regimens accordingly.

Hematopoietic stem cell transplantation (HSCT) serves as the treatment of choice for most patients with SCID.¹¹⁵ HSCT using HLA-matched related donors yields a survival rate of greater than 95%. HSCT can also be performed using HLA-haploidentical related or HLA-matched unrelated donors either with or without conditioning.^{45,58,115} However overall survival falls to 58% to 79% if transplantation is performed using cells that do not come from an HLA-matched related donor—unless infants are transplanted prior to 3.5 months of age, before infections and organ damage occur.¹¹⁵ Survival improves to 94% overall for transplants that are given before 3.5 months of age.¹¹⁵ Use or absence of conditioning does not appear to impact survival except in infants who have infections at the time of transplantation. These patients demonstrate 65% survival after HLA-haploidentical–related HSCT performed without conditioning but only 39% to 53% survival when conditioning is used.¹¹⁵

Alternative therapies may be considered for some patients. Experimental gene therapy trials were started for X-linked SCID in 1999.

Eighteen of the initial 20 recipients showed successful immune reconstitution, but 5 developed leukemia due to insertional mutagenesis of the retroviral vector within the *LMO2* oncogene.^{60,63,68} A new trial has since been initiated using a self-inactivating γ -retrovirus vector, resulting in eight survivors among nine recipients. The survivors have developed appropriate gene marking in T cells, no evidence of insertional mutagenesis, and acceptable immune reconstitution 1 to 3 years after treatment.⁶² For patients with ADA-deficient SCID, either enzyme replacement using bovine-derived polyethylene glycol-modified adenosine deaminase (PEG-ADA) or gene therapy has been used as an alternative form of treatment.^{27,51} PEG-ADA increases lymphocyte counts and provides adequate immunity in most affected patients. Most recipients, however, ultimately develop “resistance” to the drug in the form of neutralizing anti-ADA antibodies or declining lymphocyte counts over time. Gene therapy for ADA deficiency has demonstrated marked success in all clinical trials to date with no evidence of insertional mutagenesis or treatment-related leukemia.

DiGeorge Syndrome

Clinical Features

DiGeorge syndrome is characterized by facial, cardiac, parathyroid, and thymic abnormalities that can all vary to differing degrees.^{11,41,97,146} The condition may be identified early in infancy with findings unrelated to immune deficiency. Characteristic facial features include microstomia and micrognathia; hypertelorism; upturned nose; arched palate; posteriorly rotated and small, low-set ears with notched pinnae; and downward slanting of the palpebral fissures (see Fig. 67.1). Congenital heart disease, particularly truncus arteriosus and interrupted aortic arch, usually presents in the first few weeks of life and appears in almost 80% of affected children.²⁶ Neonatal hypocalcemia from hypoparathyroidism (in approximately 40% of DiGeorge infants²⁶) can result in seizures or tetany. Other defects, such as hypothyroidism, esophageal atresia, tracheoesophageal fistula, and bifid uvula, have also been described. A significant percentage of patients meet criteria for CHARGE (coloboma, heart defect, atresia or stenosis of the choanae, retardation of development or growth, genitourinary abnormality, ear malformation) syndrome or VACTERL (i.e., vertebral abnormality, anal atresia, cardiac defect, tracheo-esophageal anomaly, renal or radial defect, limb malformation) association.^{97,123} In as many as 2% of patients with DiGeorge syndrome, congenital athymia is present, resulting in the diagnosis of “complete” DiGeorge syndrome.⁸⁸ Complete DiGeorge syndrome produces a severe combined T- and B-cell deficiency that results in death from infection by 2 years of age if left untreated. However partial DiGeorge syndrome remains 50 times more prevalent and is characterized by some degree of thymic function and immune protection.

According to the degree of immune deficiency, clinical manifestations may include predisposition to a wide variety of common and opportunistic infectious diseases. Many infections are caused by neuroanatomical defects associated with DiGeorge syndrome and not by immune deficiency. Most infections tend to involve the sinopulmonary tract.^{26,38} At Texas Children's Hospital, 20% of patients with DiGeorge syndrome and mild T-cell deficiency have an increased incidence of respiratory tract infections.³³ A number of patients with DiGeorge syndrome develop hypogammaglobulinemia or humoral immunity defects that require IgG replacement therapy.^{26,116} Patients may also have difficulty with chronic diarrhea or mucocutaneous candidiasis. Recurrent or severe herpesviral infections (e.g., herpes simplex virus 1 [HSV1], cytomegalovirus), *P. jirovecii* pneumonia, and other opportunistic infections may be observed if immune deficiency is severe. Graft-versus-host disease can occur if infants receive blood products containing viable lymphocytes, often during surgical correction of heart defects. Most patients with partial DiGeorge syndrome develop adequate T-cell numbers and function by 1 year of age and do not have an increased incidence of opportunistic infections.

Pathogenesis

DiGeorge syndrome is caused by abnormal embryologic development of the third and fourth branchial arches and their derivatives, including the parathyroid glands, aortic arch structures, and the thymus gland.¹⁴⁶ The condition is most frequently associated with 22q11.2 hemizygosity,

but fewer than 60% of patients with DiGeorge anomaly have microdeletions within chromosome 22q11.^{97,123} Some patients have mutations in *CHD7*, which is associated with CHARGE syndrome.³⁸ A few patients have been reported who carry a deletion in chromosome 10p.³⁸ Fetal exposure to retinoic acid, fetal alcohol syndrome, and diabetic embryopathy can also produce DiGeorge syndrome.³⁸

Searches for single molecular causes of DiGeorge syndrome have focused on genes located within the critical chromosomal region that is deleted in patients with 22q11.2 hemizygosity. Early studies implicated *TBX1*, since mice that bear *TBX1* deletions reproduce many of the characteristic features of DiGeorge syndrome.¹⁶⁶ A role for *TBX1* may be supported by the finding that the DiGeorge phenotype, including athymia, can be reproduced by homozygous deletions in *NKX26*, which encodes a protein that mediates effector functions downstream from *TBX1*.¹⁴³ However DiGeorge syndrome is also known to occur in patients who have 22q11.2 deletions that do not affect the *TBX1* gene, suggesting that it may not provide the sole answer.¹⁵⁵ *DGCR8*, *MAPK1*, and *CRKL* lie within the 22q11 critical region, and mutations in any of these genes have also been demonstrated to reproduce the DiGeorge phenotype in both mice and humans.^{30,38,132,168} Of note, patients with partial DiGeorge syndrome have been found to display a dose-sensitive effect of *CRKL* protein expression despite normal levels of *TBX1* protein expression.¹⁶⁸ In these patients, haploinsufficiency of the *CRKL* gene is sufficient for disrupting LFA-1-mediated activation and polarization of NK cells during immunologic synapse formation with target cells. Others have shown that decreased *CRKL* expression in patients with partial DiGeorge syndrome may be associated with decreased T-cell function.⁵³ It remains intriguing to observe whether the same *CRKL* dosage effect applies to other processes, such as cardiac outflow tract formation, in patients with DiGeorge syndrome.¹²¹

Diagnosis

DiGeorge syndrome remains a clinical diagnosis. It should be suspected by the presence of characteristic facial dysmorphic features, hypocalcemia, or congenital heart disease in the neonatal period. Despite the widely used practice of excluding the diagnosis based on fluorescence in situ hybridization or other genetic testing for 22q11.2 hemizygosity, the fact that approximately 40% of patients do not have 22q11 deletions indicates that many patients will be missed or inappropriately treated if only 22q11.2 hemizygosity is considered. Thus genetic testing alone cannot be used to exclude the diagnosis.

Other laboratory testing should be performed to establish the degree of immune deficiency. Lymphopenia and T-cell numbers can vary significantly.^{26,38} Determination of naïve T-cell numbers and percentages and testing for lymphocyte proliferative responses to mitogens and antigens should be performed to distinguish complete from partial DiGeorge syndrome and to provide an assessment of overall thymic function. Imaging studies may support the presence of thymic hypoplasia or aplasia if they show absence of the thymic shadow. However, radiographic studies must also be considered in relation to any history of cardiac surgery, when total or partial thymectomy may be performed. Some patients may be observed to have low levels of IgG, IgA, or IgM, suggesting abnormal humoral immunity.³⁸ Patients should be assessed for defective specific antibody responses to immunizations to determine the potential need for IgG replacement therapy.^{26,116} However, predisposition to infections due to DiGeorge syndrome–related neuroanatomical abnormalities must always be considered.

Treatment and Prognosis

Immunologic treatment strategies should be adjusted according to the degree of immune deficiency. Initial management should always focus on the treatment of hypocalcemia and the surgical correction of any congenital heart disease. Antibiotic prophylaxis may be considered for patients with recurrent infections. In patients who have recurrent infections and defective antibody responses to immunizations, IgG replacement therapy is indicated. Children with very low CD4⁺ T-cell counts or markedly diminished T-cell responses to mitogens should receive prophylaxis against *P. jirovecii* pneumonia. Infections should be recognized early and treated promptly. Only irradiated, cytomegalovirus-negative blood products should be administered. Patients should receive

all scheduled inactivated, toxoid, recombinant, and protein-conjugated vaccines. Infants should be referred for evaluation by a clinical immunologist, however, before being administered live attenuated measles, mumps, rubella, and varicella vaccines. Oral poliovirus immunization is no longer available in the United States and is not recommended; no data are available regarding live attenuated rotavirus and influenza vaccines. Several retrospective studies have suggested that children with partial DiGeorge syndrome may safely receive live MMR and varicella immunizations if CD4⁺ T-cell counts are normal or mildly decreased but not if CD4⁺ T-cell counts are reduced to the level at which infants with HIV infection would be considered severely suppressed (less than 750 cells/mm³ if under 12 months of age and less than 500 cells/mm³ between 1 and 5 years of age).^{9,66,105,117,161} Thus administration of live measles, mumps, rubella, and varicella immunizations is not indiscriminately recommended for all DiGeorge syndrome patients.

For patients with complete DiGeorge syndrome, therapeutic options include either thymus transplantation or hematopoietic cell infusions. Thymus transplantation has been studied in greater depth and results in 70% survival.^{38,98,99} Significantly fewer patients have been treated with hematopoietic cell infusions, demonstrating approximately 40% survival.⁷⁰ Thymus transplantation, however, is only available as an experimental procedure.

Autoimmunity represents the most significant long-term immunologic complication in all patients with DiGeorge syndrome.^{26,147} It can be present in more than 10% of individuals at the time of diagnosis and increases to a prevalence of almost 25% over time. The most common manifestations include autoimmune cytopenias, thyroid disease, arthritis, hepatitis, and celiac disease.

Wiskott-Aldrich Syndrome

Clinical Features

Wiskott-Aldrich syndrome (WAS) is an X-linked disorder traditionally characterized by recurrent infections, propensity for bleeding, and eczema. However, only a minority of patients develop this classic triad of features.^{22,94,101} Fewer than 5% of patients present with only infectious manifestations.²² Recurrent otitis media (almost two-thirds of all patients) and pneumonia (25% of patients) are frequently caused by encapsulated bacteria (e.g., *S. pneumoniae*, *H. influenzae*). Septicemia, meningitis, and other serious systemic bacterial infections may also occur. Common opportunistic pathogens include *Candida*, cytomegalovirus, varicella, other herpesviruses, and *P. jirovecii*. Almost all individuals with WAS have microthrombocytopenia, which is nearly pathognomonic for the disease. As a result, bleeding complications occur in more than 80% of patients.²² Bleeding diathesis may present as easy bruisability or gastrointestinal bleeding in the first months of life. Patients have increased risk for life-threatening hemorrhages, particularly intracranially.^{22,94} Eczema is associated with increased serum IgE levels and can exacerbate the risk for skin infections.

Important long-term complications of WAS include autoimmunity and malignancy. Approximately 40% of patients with WAS develop autoimmunity.²² The most common manifestations include autoimmune hemolytic anemia, vasculitis, nephropathy, arthritis, and inflammatory bowel disease.^{22,94,101} Autoimmune platelet destruction can contribute toward the thrombocytopenia.^{22,94} Regarding malignancy, many patients with WAS develop neoplastic disease before 10 years of age.²² Lymphomas, particularly non-Hodgkin lymphoma, represent the most common malignancies. Other malignancies include myelodysplasia, leukemia, and myeloproliferative disorders.

Pathogenesis

The WAS gene is mutated in individuals with Wiskott-Aldrich syndrome and maps to the X chromosome.⁴⁰ This gene encodes a protein (Wiskott-Aldrich syndrome protein [WASP]) that is expressed in leukocytes and platelets and is important for cytoskeletal organization and formation of pseudopodia.¹⁰¹ Disrupted protein expression causes immunologic synapses to form poorly, resulting in defective interactions between antigen-presenting cells and T cells, T cells and B cells, regulatory T cells and effector cells, and T and NK cells and target cells. Most mutations in WAS that lead to Wiskott-Aldrich syndrome consist of nonsense mutations, insertions, deletions, or complex mutations.¹⁰¹ Missense

mutations have been identified toward the N-terminus of WAS that result in X-linked thrombocytopenia without or with only mild immunodeficiency.¹⁵⁶ Other missense mutations near the middle of WAS produce X-linked neutropenia with variable myelodysplasia.¹⁰¹

Diagnosis

WAS should be suspected in a male infant with microthrombocytopenia, which is best assessed by examining a peripheral blood smear because automated cell counters report only mean values. The presence of eczema or recurrent infections can support the diagnosis. Serum immunoglobulin concentrations vary, but the serum IgE level is usually elevated. Antibody responses to protein antigens (e.g., tetanus toxoid) are typically normal but can be diminished in some patients.^{22,101} Antibody responses to polysaccharide antigens (e.g., 23-valent pneumococcal polysaccharide antigen vaccine, isohemagglutinins) are characteristically absent.^{22,101} T-cell lymphopenia is often present and attributed to both abnormal T-cell development in the thymus and increased apoptosis.^{22,101} Patients with WAS often display anergy to delayed-type hypersensitivity skin testing. Approximately half of patients demonstrate low proliferative responses to mitogens.^{22,101} Antigen-specific T-cell functions, such as activation, proliferation, and cytotoxicity, are impaired in most patients.^{22,101} Neutrophils, monocytes, and other leukocytes exhibit defective chemotaxis and antibody-dependent phagocytosis. NK cell cytotoxicity is abnormally low in patients with WAS, and invariant NKT cells are notably absent. The diagnosis is ultimately confirmed by assessing WAS protein expression or sequencing of the WAS gene.

Treatment and Prognosis

Management strategies depend strongly on the severity of clinical disease. Patients with WAS are assigned a clinical score that ranges from 0 to 5 according to the presence of thrombocytopenia, eczema, immunodeficiency, autoimmunity, and malignancy.^{22,94} Patients younger than 2 years with a score of 5 have a particularly poor prognosis associated with severe refractory thrombocytopenia, autoimmune hemolytic anemia, and vasculitis.⁹⁴ They require aggressive therapy, including HSCT using HLA-matched related, HLA-matched unrelated, or haploidentical related donors. This strategy results in 65% survival for these patients.⁹⁴ Patients who have an HLA-identical sibling or patients who have a clinical score of 3 or higher should all undergo HSCT, if possible.²² Overall HSCT yields greater than 80% long-term survival for patients with WAS.²² The procedure results in normalization of cellular immunity, specific antibody responses, and platelet counts. Splenectomy may be considered for severe thrombocytopenia when HSCT is not available, but splenectomy is associated with increased morbidity and mortality following HSCT.²² Antibiotic prophylaxis directed against *S. pneumoniae* and *H. influenzae* should be given to patients who have undergone splenectomy and may be considered for patients who develop recurrent infections of the sinopulmonary tract.²² Immunoglobulin replacement therapy is indicated in patients with recurrent infections due to absent antibody responses to polysaccharide antigens. All patients with WAS should be placed on prophylaxis against *P. jirovecii* infection. In patients who develop autoimmunity, the use of immune suppressive or modulating agents must be weighed against the risk for infection.

Prognosis remains guarded in patients with WAS, even after HSCT. Leading causes of mortality include infection, bleeding, and malignancy.²² HSCT recipients carry an increased risk for viral reactivation.²² Autoimmunity continues to present as a significant cause of morbidity and has been attributed to mixed chimerism in patients who have received HSCT.^{16,101}

Gene therapy trials offer hope for improved definitive treatment of patients with WAS. Between 2006 and 2009, 10 patients were treated using a γ -retroviral vector.²⁰ Nine patients demonstrated sustained engraftment and correction of defective WAS protein expression associated with improved clinical features. However seven of nine patients developed leukemia due to insertional mutagenesis in similar fashion to the early X-linked SCID gene therapy trial.^{16,20} A new WAS gene therapy trial has since been started using a lentiviral vector to treat seven patients. Six have survived (one died from herpesviral infection). The six survivors have shown successful engraftment, WAS protein expression, clinical and immunological improvement, and no evidence of insertional mutagenesis.^{1,61}

Ataxia-Telangiectasia

Clinical Features

Ataxia-telangiectasia is characterized by cerebellar ataxia, oculocutaneous telangiectasias, variable immunodeficiency with frequent infections, and a high incidence of malignancy.^{35,142,144} Ataxia usually becomes evident between 1 to 2 years of age. Progressive choreoathetosis, myoclonic jerking movements, and oculomotor abnormalities subsequently develop, resulting in severe disability. Telangiectasias appear on the bulbar conjunctivae, usually in patients between 2 and 5 years of age (see Fig. 67.2). They subsequently appear on the nasal bridge, ears, and other areas of sun exposure or trauma. Other cutaneous manifestations include café-au-lait spots, vitiligo, necrobiotic noninfective granulomas, and prematurely gray hair. Most patients develop recurrent infections of the sinopulmonary tract; systemic infections rarely occur despite immunologic abnormalities. Pathogens frequently identified in pediatric patients include *Staphylococcus aureus*, *Haemophilus influenzae*, and *Streptococcus pneumoniae* while older patients are susceptible to *Pseudomonas aeruginosa*.¹²⁹ Almost 25% of patients with ataxia-telangiectasia develop malignancies, of which the most prevalent include B-cell non-Hodgkin lymphoma, leukemia, and solid organ carcinomas (especially of the breast and stomach).^{142,144}

Pathogenesis

Ataxia-telangiectasia is inherited in an autosomal recessive manner. The defective gene (*ATM*) responsible for the disease maps to chromosome 11.¹²⁷ Various domains of the ATM protein play different roles in cellular responses, including cytokine signaling. ATM is critically involved in DNA damage checkpoint control and repair.³¹ Immune deficiency in ATM patients is attributed to impairment of DNA repair during rearrangements required for expression of the T-cell receptor genes and B-cell immunoglobulin heavy-chain genes. Abnormal repair mechanisms result in radiosensitivity. Impaired checkpoint control and defective repair activities together likely contribute to the increased risk for malignancy.

Diagnosis

Ataxia-telangiectasia can be diagnosed in a variety of manners.¹⁴⁴ A clinical diagnosis is possible when the disease is fully manifested. Increased serum α -fetoprotein concentrations are observed in essentially all patients older than 6 months of age. Serum IgG levels can be normal or slightly low, while IgA deficiency is frequently observed.³⁵ Some patients may have elevated levels of IgM, which usually exists in a monomeric 7S form rather than the usual pentameric 19S molecule. Specific antibody responses correlate with the level of ATM kinase activity.⁴³ They often remain intact, although they may decline in some patients as they age.³⁵ T- and B-cell numbers can be low in approximately two-thirds of patients.^{35,77} Patients may exhibit delayed-type hypersensitivity skin test anergy, and about one-third of patients can have reduced decreased lymphocyte proliferative responses to mitogens.⁷⁷ Patients cells will typically demonstrate decreased survival in clonogenic or other radiosensitivity assays. Definitive diagnosis should be confirmed through sequencing of the *ATM* gene.

Treatment and Prognosis

No specific treatment is available for ataxia-telangiectasia because the pathologic processes involve multiple body systems. Infections should be treated with oral or parenteral antibiotics. Continuous prophylactic antibiotic therapy may benefit individual patients. Immunoglobulin replacement therapy should only be given to patients with recurrent infections and abnormal specific antibody responses. Patients should be advised to minimize exposure to ionizing radiation. Median survival ranges from 19 to 25 years of age, although patients who have less deleterious *ATM* mutations may survive into the fourth decade of life.¹⁴⁴ Important causes of mortality include interstitial or chronic pulmonary disease and malignancies.^{142,144}

PRIMARY COMPLEMENT DEFICIENCIES

Clinical Features

Complement deficiencies are rare PIDDs that lead to increased susceptibility to infections or autoimmunity. All patients demonstrate increased

susceptibility to infections by *N. meningitidis*.⁵⁷ Primary complement deficiencies can be identified in up to 20% of patients with invasive meningococcal disease, and the likelihood of having complement deficiency increases significantly to about 30% in individuals who have had more than one infection.^{7,57,102} Patients who have deficiencies of early classical complement pathway components (i.e., C1, C4, C2, and C3) are also susceptible to infections by other encapsulated bacteria, including *S. pneumoniae* and *H. influenzae*.⁵⁷ C2 deficiency represents the most common complement pathway deficiency and is estimated to occur at a prevalence of one in 20,000 individuals. Fewer than 40% of patients with C2 deficiency develop autoimmunity; approximately 1% of patients with SLE have been found to have C2 deficiency.⁵⁷ C1q deficiency is the next most common early pathway complement deficiency. About 95% of patients with C1q deficiency develop severe autoimmune disease.⁵⁷ C4 and C3 deficiencies are very rarely observed. C4 deficiency is associated with increased risk for autoimmunity while C3 deficiency is not.⁵⁷ In patients with deficiencies of terminal complement components (C5 through C9), *Neisseria meningitidis* remains the most significant bacterial cause of infection.^{7,57} Patients with terminal complement protein deficiencies have increased risk for recurrent episodes of septicemia and meningitis; about 40% of patients develop neisserial meningitis.⁵⁷ C5 deficiency is the most rare terminal complement pathway deficiency and is also associated with the development of SLE.⁵⁷ C9 deficiency may not be uncommon, and most affected individuals are asymptomatic.⁵⁷ Properdin is another complement component that functions in the alternative pathway. Patients with properdin deficiency demonstrate increased risk for *Neisseria meningitidis* infections, and approximately 6% develop neisserial meningitis.⁵⁷ Mannose-binding lectin deficiency has been proposed as a complement pathway defect that leads to recurrent pyogenic infections. However its essential role as a primary cause of PID remains controversial because a significant percentage of healthy individuals (about 5%) are known to have mannose-binding lectin deficiency.⁵⁷

Pathogenesis

Various gene defects are responsible for the many distinct primary complement deficiencies. C3 is an important opsonin that promotes ingestion and killing of bacteria. As a consequence, patients with C3 deficiency have increased susceptibility to encapsulated bacterial infections (e.g., *S. pneumoniae*, *H. influenzae*), for which opsonization serves as a critical mechanism of host defense. Individuals with deficiencies of C1, C4, or C2 also have increased susceptibility to these encapsulated bacteria because these components are necessary for activation of C3 in the classical pathway. Activation of terminal complement components C5, C6, C7, C8, and C9 results in assembly of the membrane attack complex, a multicomponent macromolecule that results in membrane pore formation and lysis. Only gram-negative bacteria, such as *N. meningitidis*, are susceptible to this bactericidal effect. The gene for properdin is found on the X chromosome; properdin deficiency is the only complement pathway defect that is inherited in an X-linked recessive manner. Properdin stabilizes the C3-factor B complex in the alternative pathway. Mechanisms for increased risk for autoimmunity remain unclear. B cells express CD21, which is a receptor for activated products of C3 and plays a role in regulating transport of immune complexes in follicles. Dysregulation of this process may contribute toward development of autoimmunity.

Diagnosis

The CH50 reflects the combined activity of all numbered components of the classic complement pathway from C1 through C9. Thus a patient with a classical complement pathway deficiency will have a very low CH50. In similar fashion, the AH50 can be used to assess the alternative complement pathway. Specific immunochemical and functional testing can then be performed to identify the deficient component. Deficiency is defined as a serum level of 0 or close to zero for any given component. All of these tests, including specific component testing, can be easily affected by sample conditions, and the most common cause of an abnormal result is sample mishandling.⁵⁷

Treatment and Prognosis

No specific therapy exists for primary complement deficiencies. Both polysaccharide and protein-conjugated meningococcal vaccines are

BOX 67.5 Primary Phagocyte Deficiencies

Quantitative Defects

Infantile agranulocytosis
Familial granulocytopenia
Cyclic neutropenia

Qualitative Defects

Adhesion Defects

Leukocyte adhesion deficiency:

- Type I, β -integrin deficiency
- Type II, fucose-transporter deficiency
- Type III, *FERMT3* deficiency

Intracellular Killing Defects

Chronic granulomatous disease:

- X-linked
- Autosomal recessive

Glucose-6-phosphate dehydrogenase deficiency
Myeloperoxidase deficiency
Chédiak-Higashi syndrome
Griscelli syndrome

recommended.⁵⁷ Antibiotic prophylaxis and immunizations against other encapsulated organisms may be beneficial. Close surveillance for autoimmunity is recommended for patients with C1, C2, C4, and C5 deficiencies.

PRIMARY PHAGOCYTE DEFICIENCIES

Primary phagocyte deficiencies include a heterogeneous group of disorders sharing a common susceptibility for frequent infections due to either a decreased number of phagocytic cells (e.g., neutropenia), impaired adhesion, chemotaxis, opsonization, and phagocytosis, or defective intracellular killing (Box 67.5). Affected patients tend to have prolonged and recurrent infections with slower responses to antibiotic therapy than expected. Common pathogens include *S. aureus*, *P. aeruginosa*, enteric gram-negative bacteria, and certain fungi (e.g., *Aspergillus* spp.).

Quantitative Phagocyte Abnormalities

Primary quantitative phagocyte deficiencies can be observed as solitary defects or in association with other disorders (e.g., Shwachman syndrome). Severe congenital neutropenia (i.e., Kostmann syndrome⁷²) is characterized by arrest of granulocyte maturation, markedly decreased numbers of circulating granulocytes, and severe infection. Severe congenital neutropenia syndromes are caused by mutations in the leukocyte elastase (*ELANE*), *HAX1*, *G6PC3*, *GFI1*, *JAGN1*, *CSF3R*, and *WAS* genes.^{17,19} The more benign familial granulocytopenia syndrome manifests at various ages from infancy to adulthood, usually with indolent infections of the skin and soft tissues.

Cyclic neutropenia is an autosomal dominant defect of myelopoiesis in which periodic disappearance of granulocytes from the circulation occurs. The condition is caused by mutations in *ELANE*.⁹⁵ Early granulocyte precursors are present in the bone marrow during periods of neutropenia, suggesting transient maturation arrest. Periods of neutropenia usually last 5 to 7 days and occur at 14- to 35-day intervals. The length of the cycle generally remains constant for any given individual. Fever and malaise are often observed during periods of neutropenia. Patients demonstrate increased episodes of aphthous stomatitis, pneumonia, abscesses, sepsis, cellulitis, and peritonitis.⁹⁵ Certain mutations in *ELANE* appear to predispose to development of myelodysplasia or acute myeloid leukemia.⁹⁵

Some of the primary quantitative phagocyte deficiencies, particularly familial granulocytopenia and cyclic neutropenia, respond to therapy with recombinant granulocyte colony-stimulating factor.⁹⁵

Chronic Granulomatous Disease

Clinical Features

Patients with CGD develop infections that begin during infancy and recur throughout their lives. Occasionally, patients display a relatively mild disease course and come to medical attention only during adolescence or adulthood. Infections of the lungs, skin, lymph nodes, and liver present as the most frequent initial manifestations of CGD.⁶⁷ Patients also demonstrate susceptibility to soft tissue abscesses, perirectal abscesses, central nervous system infections, and osteomyelitis.⁴⁷ Infections in patients with CGD may progress with few symptoms, and the erythrocyte sedimentation rate and C-reactive protein levels may provide the most sensitive signs of active infection.⁴⁷ Patients with CGD are susceptible to infections caused by catalase-positive organisms. For infections in the United States in which a responsible organism can be identified, most episodes are caused by *S. aureus*, *Burkholderia cepacia*, *Serratia marcescens*, *Klebsiella pneumoniae*, *Nocardia*, and *Aspergillus* spp.^{67,96} In many cases, no organism can be isolated. Outside of the United States, *Salmonella*, BCG, and *M. tuberculosis* serve as additional important pathogens.⁶⁷ Fungi, especially *Aspergillus* spp., account for 20% to 40% of all defined infections in patients with CGD (Fig. 67.6).⁴⁷ CGD is particularly characterized by infections due to unusual organisms. Examples include *Chromobacterium violaceum*, *Francisella philomiragia*, *Aspergillus nidulans*, *Paecilomyces variotii*, *Paecilomyces lilacinus*, *Neosartorya udagawae*, methylotrophic bacteria, and a variety of other fungi.^{47,48,64,67} An infection caused by any of these organisms should be considered pathognomic for a diagnosis of CGD until proved otherwise. Of note, patients with CGD do not carry increased susceptibility to *Candida*.⁶⁴

Patients with CGD also develop important noninfectious complications.⁶⁷ Poor wound healing can be observed. Granulomatous obstructive lesions of the urinary and gastrointestinal tracts occur frequently. More than 40% of patients with X-linked CGD develop an inflammatory bowel disease that mimics Crohn disease.⁶⁷ Hepatic dysfunction can lead to portal hypertension, splenomegaly, and splenic sequestration. A small percentage of boys with X-linked CGD have the McLeod blood phenotype, characterized by absence of the Kell antigen in red blood cells as a consequence of a contiguous gene deletion, which results in difficult crossmatching for blood transfusion and the potential for hemolytic transfusion reactions.²¹ Female carriers of a mutated X-linked CGD gene can also develop inflammatory or autoimmune clinical features, such as photosensitivity, autoimmune arthritis, discoid lupus erythematosus, aphthous stomatitis, Raynaud's phenomenon, inflammatory colitis, and chorioretinitis.¹³

FIG. 67.6 Chest radiograph of a 10-year-old boy with chronic granulomatous disease shows a left-sided pulmonary infiltrate and cavitory lung lesion. Biopsy revealed an *Aspergillus fumigatus* infection.

Pathogenesis

CGD is caused by mutations in genes that encode membrane or cytosolic components of the nicotinamide adenine dinucleotide phosphate oxidase (NADPH oxidase) complex system. The most common defect occurs in gp91^{phox}, which is encoded by *CYBB* on the X chromosome and accounts for almost two-thirds of cases of CGD.^{34,67} Mutations in genes encoding the other components (p47^{phox}, p67^{phox}, p22^{phox}, and p40^{phox}) have also been reported and are inherited in an autosomal recessive manner. p47^{phox} deficiency accounts for 25% to 30% of cases of CGD.^{34,67} Defective NADPH oxidase function results in failure to generate the respiratory burst required for killing of phagocytized organisms. Inappropriate production of reactive oxygen species is also felt to contribute to dysregulated inflammation, resulting in many of the noninfectious complications.

Diagnosis

The diagnosis of CGD is made using the flow cytometry-based DHR chemiluminescence assay. Falsely abnormal DHR test results can be observed in patients who have myeloperoxidase deficiency, SAPHO syndrome, G6PD deficiency, or neutrophils that are highly activated due to significant infection.⁶⁷ The DHR assay can detect females who are carriers for X-linked CGD and is often able to differentiate X-linked CGD from autosomal recessive forms. Genotyping is not required to confirm the diagnosis but may be helpful for determining prognosis.⁶⁷

Treatment and Prognosis

Because infectious organisms often cannot be isolated in patients with CGD, empirical antibiotic therapy is frequently used to treat infections. Still, specific microbiologic diagnoses for infections should always be established whenever possible. Due to dysregulated inflammatory processes, patients who develop infections may not present until they become very ill. Thus a low threshold should be placed for suspecting the presence of an infection. Elevated erythrocyte sedimentation rates and C-reactive protein levels should warrant concern for infection. Experience with a large cohort of patients with CGD suggests that serum galactomannan and 1,3-β-D-glucan levels may not be useful for assessing fungal infections in patients with CGD.⁴⁷ Empirical therapy should be directed against the organisms known to commonly cause infections, such as *S. aureus*, *S. marcescens*, *K. pneumoniae*, *Nocardia*, *Aspergillus* spp., and *Salmonella*. Most patients are susceptible to methicillin-sensitive *S. aureus* and do not require empirical therapy for methicillin-resistant strains. Surgical drainage or debridement of infection sites is often necessary. However surgical removal of abscesses, especially of the liver, is not recommended.⁶⁷ Hepatic abscesses can be treated with a combination of antibiotics and corticosteroid therapy.⁸⁴ Granulocyte transfusions may be helpful for treating infections that do not respond to antibiotics.

Definitive cure is provided by HSCT.^{67,100} Gene therapy trials for X-linked CGD in humans have resulted in increased numbers of gene-corrected, autologous neutrophils associated with resolution of infections in all patients treated. However only three patients (25%) maintained high numbers of gene-corrected cells in the long term, and all three patients developed clonal expansions associated with insertional activation of the *EVII* gene.⁵⁴ Thus gene therapy strategies for treatment of CGD are currently being modified.

All patients with CGD who have not received definitive therapy require continuous prophylaxis to prevent infections.⁶⁷ Antibiotic prophylaxis using cotrimoxazole reduces the frequency of bacterial infections in patients with CGD. Itraconazole prophylaxis should be given to prevent fungal infections.⁴⁷ Administration of IFN-γ to decrease the rate of infection is practiced in some centers but not others and remains controversial.⁶⁷ Patients should be educated about avoiding activities that expose them to environments containing mold spores, such as mulching or raking leaves.

Therapy for noninfectious complications remains challenging. Options usually include corticosteroid therapy or other immune modulating antiinflammatory medications. TNF-α inhibitors should not be used because they markedly increase the risk for infection and mortality.^{67,150}

The prognosis for CGD has improved remarkably during the past several decades, and most patients (approximately 90%) now survive to adulthood.⁶⁷ Morbidity and mortality strongly depend on fungal infections and residual NADPH oxidase activity.^{67,96} Patients with autosomal recessive forms of CGD tend to have greater superoxide production, a milder disease course, and better long-term survival.⁶⁷ Patients with p47^{phox} deficiency appear to have the best prognosis. Even among patients with X-linked CGD, rates of long-term survival are higher in those patients with greater residual superoxide production, whereas patients with no residual superoxide production demonstrate the lowest likelihood for long-term survival.⁶⁷

Leukocyte Adhesion Deficiency

Clinical Features

Patients with LAD develop severe and recurrent bacterial infections of the skin and soft tissues, mucosal surfaces, and gastrointestinal tract, often beginning during early infancy.¹⁵¹ Early presentation includes delayed separation of the umbilical cord that is associated with omphalitis. Patients later develop cutaneous infections that manifest as nonpurulent inflamed tissues that often become necrotic, resembling ecthyma gangrenosum or pyoderma gangrenosum. Absence of purulence is a hallmark feature of the disease. Poor wound healing is present. Patients can also develop severe gingivitis and periodontitis with progressive alveolar bone loss (see Fig. 67.3). Common pathogenic microorganisms include staphylococci and *Pseudomonas* spp.

Patients with LAD classically demonstrate marked leukocytosis. Circulating neutrophil counts may range between 15,000/mm³ and 75,000/mm³, even in the absence of infection; and counts of 100,000/mm³ or greater can be observed during infections.

Pathogenesis

LAD type I is an autosomal recessive disorder due to mutation in *ITGB2* on chromosome 21. Neutrophils from individuals with LAD type I exhibit defective expression of surface glycoproteins known as the leukocyte-integrin complex. These molecules are critical for adhesion-dependent functions, and their absence is responsible for defects in leukocyte adherence, chemotaxis, and phagocytosis. The severity of infectious complications in LAD is related directly to the degree of CD18 expression.^{148,151} Patients with the severe clinical phenotype demonstrate less than 2% expression of these complexes on their phagocytes, whereas individuals with the moderate phenotype generally have 2% to 30% expression, explained by missense gene mutations that allow surface expression of a defective protein.

Other forms of LAD have been reported. A rare second form of LAD is associated with craniofacial dysmorphism, neurologic deficits, recurrent respiratory tract infections, and marked leukocytosis.⁴⁶ Neutrophils from patients with LAD type II have normal surface expression of CD18. The molecular basis for the phagocyte dysfunction is a defect in the fucose transporter that mediates glycosylation of sialyl-Lewis X, a carbohydrate ligand for the endothelial adhesion molecules E-selectin and P-selectin. A third form of LAD has been described, characterized by deficient β -integrin-mediated activation due to mutations in *FERMT3*, which encodes a protein necessary for inside-out signaling transduction. It is associated with bleeding tendency and osteopetrosis.

Diagnosis

The diagnosis of LAD type I is made by flow cytometry using fluorescence-labeled monoclonal antibodies to CD18.¹⁵¹ Supporting studies reveal abnormalities of phagocyte adherence, chemotaxis, and phagocytosis but are not required. Individuals with LAD type II have similar phagocyte function abnormalities with normal expression of CD18 but decreased expression of CD15 on leukocytes. LAD type III is characterized by altered expression of β -integrins but remains difficult to assess in clinical laboratories. Ultimately the diagnoses of LAD types I, II, or III should be confirmed by genetic mutation analyses.¹⁵¹

Treatment and Prognosis

Few therapeutic options are available for the treatment of patients with LAD.¹⁵¹ Bacterial infections in patients with LAD must be treated

aggressively with prolonged courses of parenteral antibiotics. Granulocyte transfusions can be used to help treat infections that do not respond to antibiotics. Antibiotic prophylaxis and universal hygiene measures are recommended. For patients with LAD type II, administration of fucose can result in enhanced leukocyte function, resolution of infections, and even improved psychomotor abilities. For patients with LAD type I who do not receive definitive therapy, survival to adulthood is possible, but almost one-half of affected individuals die before reaching the second decade of life. HSCT offers the best hope for long-term survival, demonstrating an overall survival rate of 75%.¹⁵¹ Gene therapy has not yet demonstrated success for treating human LAD.

Other Primary Phagocyte Deficiencies

Other defects of phagocyte chemotaxis, phagocytosis, and intracellular killing are known and include Chédiak-Higashi syndrome, which is a rare autosomal recessive disorder characterized by partial oculocutaneous albinism, rotatory nystagmus, and peripheral neuropathy.⁴² In Chédiak-Higashi syndrome, giant peroxidase-positive granules are found throughout the body in different cell types, including leukocytes. Neutrophils exhibit defective chemotaxis and abnormal bactericidal activity. Affected individuals develop recurrent infections of the lungs, skin, and gingival tissues caused by *S. aureus* and other bacteria. Chédiak-Higashi syndrome is caused by mutations in the *LYST* gene. It is a known cause of hemophagocytic lymphohistiocytosis (HLH), which is characterized by fevers, hepatosplenomegaly, lymphadenopathy, lymphocytic infiltration of multiple organs, and progressive pancytopenia.

OTHER INNATE IMMUNITY DEFICIENCY DISEASES

In addition to complement and phagocytic deficiencies, other defects in innate immunity are becoming more frequently recognized as important causes of PIDDs. Examples include NK deficiencies, hyper-IgE syndrome, and defects in the IRAK4-MyD88 signaling pathway.

NK-cell deficiencies fall into two categories: classical and functional.¹¹⁰ Classical NK-cell deficiencies are identified by lack of NK cells and absence of NK-cell cytotoxicity. Affected patients are susceptible to herpesviral infections, such as varicella, cytomegalovirus, HSV1, and Epstein-Barr virus (EBV). The most common classical NK-cell deficiencies are caused by mutations in *GATA2* and *MCM4*. Functional NK-cell deficiencies, however, are defined by the presence of normal numbers of NK cells that exhibit abnormal function. Like patients with classical NK-cell deficiencies, patients with functional NK-cell deficiencies demonstrate susceptibility to infections by herpesviruses. They also have difficulty with human papillomavirus (HPV) and respiratory virus infections. The only identified associated cause is an L66H mutation in the *FCGR3A* gene that encodes CD16. NK cells from patients with this condition display abnormal natural cytotoxicity but normal antibody-dependent cellular cytotoxicity. No definitive therapies are available to cure patients who have NK-cell deficiencies. Most approaches focus on the use of acyclovir or related medications to treat herpesvirus infections. HPV immunization should be strongly considered for all patients who have NK-cell deficiency.

Hyperimmunoglobulinemia E (hyper-IgE) syndrome is a rare PIDD that is estimated to affect 1 in 100,000 individuals.¹⁰⁴ It is characterized by markedly elevated serum IgE levels, eczema, and recurrent infections and exists in either autosomal dominant or autosomal recessive forms. Autosomal dominant hyper-IgE syndrome is caused by mutations in the *STAT3* gene.⁷¹ STAT3 deficiency is marked by recurrent noninflammatory staphylococcal abscesses, pneumonias that result in pneumatocele formation, and chronic mucocutaneous candidiasis. Pneumatocele formation may result in chronic infection by *Pseudomonas aeruginosa*, atypical mycobacteria, or *Aspergillus*.¹⁰⁴ Viral infections do not serve as a distinguishing manifestation of STAT3 deficiency.⁷¹ Noninfectious characteristics include coarse facial features, delayed shedding of primary dentition, recurrent bone fractures, scoliosis, osteoporosis, joint hyperextensibility, and coronary artery dilatation or aneurysms.¹⁰⁴ Patients with STAT3 deficiency carry increased risk for developing malignancies, especially non-Hodgkin lymphoma. Laboratory studies may demonstrate an elevated serum IgE level, eosinophilia, and antibody deficiency.^{71,104}

Absence of T_H17 cells is nearly pathognomonic. Autosomal recessive hyper-IgE syndrome, on the other hand, is caused by mutations in *DOCK8* or—much more rarely—*TYK2*. Patients with *DOCK8* and *TYK2* deficiency do not share the noninfectious manifestations present in *STAT3* deficiency. *DOCK8* deficiency produces marked susceptibility to viral infections of the skin, including HSV1, HPV, molluscum contagiosum, and varicella.¹⁴¹ Affected patients also develop chronic mucocutaneous candidiasis, recurrent sinopulmonary infections to encapsulated bacteria, staphylococcal skin abscesses, and gastrointestinal infections. *DOCK8* deficiency is further characterized by significant atopic disease, autoimmunity (i.e., hemolytic anemia or vasculitis), and increased risk for developing malignancies, particularly squamous cell carcinomas or lymphomas. No therapies have demonstrated consistent success for definitive treatment of hyper-IgE syndrome, although HSCT has been attempted in limited numbers of patients with *STAT3* and *DOCK8* deficiencies.^{104,141} Prophylactic use of antibiotics is recommended to prevent staphylococcal infections. Bleach baths should be encouraged. Patients who have chronic mucocutaneous candidiasis may require indefinite antifungal therapy. Immunoglobulin replacement may be indicated as a therapy for patients who have recurrent infections due to defective antibody responses to immunizations.

Finally, deficiencies of *IRAK-4* and *MyD88* can cause PIDDs, especially in children.^{118,158} *IRAK-4* and *MyD88* are adaptor molecules that mediate signaling downstream from all Toll-like receptors (TLRs) except *TLR3* and (partially) *TLR4*. Patients with *IRAK-4* or *MyD88* deficiency are susceptible to a variety of infections, including meningitis, sepsis, arthritis, osteomyelitis, lymphadenitis, staphylococcal skin abscesses, and deep tissue upper respiratory tract infections. These infections are most commonly caused by *S. aureus*, *S. pneumoniae*, and gram-negative bacteria such as *P. aeruginosa*, *H. influenzae*, *Salmonella*, *Shigella sonnei*, and *N. meningitidis*. *IRAK-4* and *MyD88* deficiencies do not lead to increased susceptibility to mycobacteria, viruses, fungi, or *Pneumocystis*. No consistent laboratory findings help to identify *IRAK-4* or *MyD88* deficiency, although testing of TLR function may reveal some abnormalities. Some patients demonstrate defective antibody responses to polysaccharide antigens. Genetic sequencing of *IRAK4* but not *MYD88* is clinically available. Therapy focuses on aggressive treatment of infections, antibiotic prophylaxis, assiduous administration of immunizations, and immunoglobulin replacement for patients who exhibit poor antibody responses to immunizations. *IRAK-4* and *MyD88* deficiencies lead to high mortality in infancy and childhood, but the rate of infections interestingly decreases markedly over time in survivors for reasons that remain unclear but which may be related to enhanced adaptive immune responses.

ASSOCIATIONS BETWEEN SPECIFIC PATHOGENS AND PIDDs

In patients who demonstrate increased susceptibility to certain pathogens, a number of PIDDs may be more likely to be present than others (Table 67.5).¹⁷

Recurrent or recalcitrant candidal infections can occur in patients with PIDDs. Candidal susceptibility can signify the presence of a severe T-cell (e.g., SCID, complete DiGeorge syndrome) or T_H17 -cell (e.g., *STAT3* deficiency, *DOCK8* deficiency) defect. Alternately, defects in critical innate immunity proteins (e.g., *STAT1*, *Dectin-1*, *CARD9*) can lead to recurrent or severe candidal infections. Finally chronic mucocutaneous candidiasis associated with autoimmune polyendocrinopathy may be due to mutations in the autoimmune regulator (*AIRE*) gene, resulting in a condition known as autoimmune polyendocrinopathy ectodermal dystrophy (APECED).^{50,106}

Susceptibility to EBV often suggests deficiencies in cytotoxic ($CD8^+$) T cells or NK cells. Examples of T-cell deficiency again include SCID and complete DiGeorge syndrome. Defective NK-cell function associated with EBV susceptibility can be observed in patients who have mutations in *MCM4* and all of the genes associated with HLH or HLH-like disease (e.g., *PRF1*, *UNC13D*, *STX11*, *STXBP2*, *LYST*, *RAB27A*, *AP3B1*). The X-linked lymphoproliferative (XLP) syndrome represents a defect in control of EBV infection. Mutations in *SH2D1A*, which encodes a factor (SAP) involved in the signal transduction of T cells, have been identified as causes of XLP.^{47,111} Absence of SAP affects the interaction of T and B cells,

TABLE 67.5 Key Primary Immunodeficiency Diseases Associated With Increased Susceptibility to Specific Pathogens

Pathogen	Gene Defect
<i>Candida</i>	Genes associated with SCID, complete DiGeorge syndrome (gene unknown), <i>CIITA</i> , <i>RFX5</i> , <i>RFXAP</i> , <i>RFXANK</i> , <i>STAT3</i> , <i>DOCK8</i> , <i>IL17RA</i> , <i>IL17RC</i> , <i>IL17F</i> , <i>ACT1</i> , <i>AIRE</i> , <i>MST1</i> , <i>PTPN6</i> , <i>SP110</i> , <i>DECTIN1</i> , <i>CARD9</i> , <i>RORC</i> , <i>STAT1</i> (gain of function), <i>MAP3K14</i> , <i>BCL10</i> , <i>ITGB2</i>

leading to an inability to control B-cell proliferation caused by EBV infection.^{55,128} At presentation, males may have severe and often fatal infectious mononucleosis or B-cell lymphoma. Defects in the closely related *BIRC4* (encoded by *XIAP*) and *ITK* produce a similar phenotype.

Susceptibility to HSV1 is present in patients with severe T-cell deficiencies but more typically suggests a defect in NK cell or innate immunity function. An important example of NK-cell deficiency includes *MCM4* deficiency. Mutations in *TLR3*, *TRIF*, *UNC93B1*, *TRAF3*, and *TBK1* lead to increased susceptibility to HSV1 encephalitis.

Several PIDDs are known to be associated with increased susceptibility to HPV infection. HPV infection is frequently observed in patients with SCID, especially X-linked SCID, but not in complete DiGeorge syndrome patients. NK-cell deficiencies, such as *GATA2* and *MCM4* deficiencies predispose to HPV infection. Disseminated cutaneous HPV infection (warts) can also develop in patients with mutations in *EVER1* or *EVER2*. Autosomal dominant gain-of-function mutations in *CXCR4* result in warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM) syndrome. This condition is characterized by neutropenia, B-cell lymphopenia, and hypogammaglobulinemia, leading to recurrent sinopulmonary, urinary tract, cutaneous, and invasive bacterial infections. In patients with WHIM syndrome, HPV infections can progress to malignancy.

Increased susceptibility to atypical mycobacteria is also observed in patients with certain PIDDs. Atypical mycobacterial infections have been observed in patients with severe T-cell deficiencies (e.g., SCID, complete DiGeorge anomaly, *FOXN1* deficiency) in the form of disseminated BCG infection after vaccination. Defects in the $IFN-\gamma$ -IL-12 pathway also result in susceptibility to severe atypical mycobacterial infections. Examples include mutations in the $IFN-\gamma$ receptor genes (i.e., *IFNGR1*, *IFNGR2*)¹²⁴ and genes for IL-12 and the IL-12 receptor.⁴

These lists are by no means exhaustive and change rapidly as novel PIDDs are discovered or new clinical cases are reported. Thus clinicians must maintain a high index of suspicion for various PIDD diagnoses

based on other clinical and laboratory findings, even if one of these infectious susceptibilities is either present or absent.

CONCLUSION

PIDDs are no longer considered rare diseases in children. Soon mutations in well over 300 genes will have been identified as causes of PIDDs, resulting in improved recognition of the pathogenesis of many of these conditions.

Scientific and medical advances have led to enhanced care of children with PIDDs, allowing them to survive well past childhood, with a quality of life that continues to improve. Early identification of these children remains critical, and medical providers must strongly suspect and investigate the presence of PIDDs in children who have infections of abnormal severity or frequency or in children who develop infections caused by unusual or highly characteristic organisms. Associated infections range from sinopulmonary tract infections that sometimes occur in patients with IgA deficiency to life-threatening opportunistic infections that appear during the first weeks of life, such as in SCID. The initial immunologic screening consists of widely available laboratory tests. Prompt referral to a clinical immunologist is warranted when any PIDD is suspected. Newborn screening for SCID has successfully identified patients who have severe T-cell deficiencies before significant infections occur, allowing for early, definitive, life-saving treatment and minimization of morbidity and mortality. Although still experimental, gene therapy has continued to progress in clinical trials for X-linked SCID, ADA-deficient SCID, WAS, and CGD, with valuable lessons learned. Successful results in these trials demonstrate continued promise for cure of many other PIDDs at some time in the future.

The Febrile Neutropenic Patient

68

Brian T. Fisher • Lillian Sung

Since chemotherapeutic agents were first administered for the treatment of malignancy, infection has been a cause of significant morbidity and mortality. Initial reports documented an infection-related mortality rate among patients with acute leukemia that was greater than 70%.^{65,68} In the past five and one-half decades, cancer survival rates have improved dramatically in high-income countries, with more than 80% of children with cancer surviving beyond 5 years from diagnosis.^{6,168} However, the immunosuppressive consequences of chemotherapy continue to exist, and infections still account for a substantial number of deaths in children receiving intensely myelosuppressive chemotherapy,¹⁵² especially in the 2 weeks after diagnosis.³⁵

For many decades, researchers have sought to identify risk factors for infection and to devise risk-stratified therapeutic approaches to reduce infectious mortality rates in patients receiving chemotherapy. Early descriptive pediatric studies confirmed that the depth and duration of neutropenia was a risk factor for developing infection. Furthermore fever was a frequent and sometimes the only clinical sign indicating the presence of infection in this at-risk population.⁶⁸ In these early years, fever in patients with neutropenia prompted an infectious evaluation, but empiric antibiotic therapy was not considered standard of care. Because infection was the most common cause of fever in neutropenic patients and because some patients with fever and neutropenia had rapid progression to death, particularly due to *Pseudomonas aeruginosa* bacteremia, empiric therapy was explored. In 1971, Schimpff et al. published one of the sentinel experiences of combination empiric therapy with carbenicillin and gentamicin in a series of patients with fever and neutropenia.¹⁴² Their efforts revealed a reduction in infectious mortality with this approach relative to historical controls. Specifically, in the historical control period, when empiric antibiotic therapy was not utilized, 20 of 22 *P. aeruginosa* infections ultimately resulted in death. This compared to only four deaths out of 21 *P. aeruginosa* infections during the study period. Subsequent landmark trials by Pizzo et al. supported the continuation of empiric antibiotics through the duration of neutropenia and prompted the addition of empiric antifungal therapy in the setting of prolonged fever and neutropenia despite broad-spectrum antibiotic therapy.^{122,123}

In the decades that followed, empiric antibacterial and antifungal therapy has evolved into standard of care for patients with fever and neutropenia. Clinical practice guidelines from various societies have better standardized the approach to this clinical scenario.^{38,54,88,102} Although these guidelines have been useful, they have primarily focused on adult patient populations. This has left pediatricians to apply guidelines that have not accounted for important differences between children and adults presenting with fever and neutropenia.¹⁵⁴ Fortunately, in 2012, an international group of investigators formed the Pediatric Fever and Neutropenia Guideline Panel with the objective of systematically

reviewing the available literature to inform an evidence-based guideline for the management of the child with fever and neutropenia. The initial version of this guideline addressed a number of the important differences in the management of pediatric and adult patients with fever and neutropenia.⁸⁹ In addition to providing guidance on current management practices, the committee identified knowledge gaps with the goal of directing future investigation that will provide further data to improve the breadth of evidence-based clinical practice.

This chapter focuses on the epidemiology of fever and neutropenia and approaches for risk stratification that are pertinent to pediatric patients. Advances in modalities for diagnosing bacterial and fungal infections are also explored. Finally empiric, preemptive, and prophylactic therapeutic interventions are reviewed. At relevant points, areas for necessary future investigation are highlighted. There are many other etiologies of neutropenia (e.g., congenital neutropenia and autoimmune neutropenia),¹²⁹ and such patients will also incur periods of fever and neutropenia. However, the importance of fever in these settings varies substantially and thus the focus of this chapter is on fever in the setting of chemotherapy-induced neutropenia.

EPIDEMIOLOGY OF FEVER AND NEUTROPENIA

Children receiving chemotherapy are often confronted with at least one episode of fever and neutropenia during the course of their cancer care. The frequency of fever and neutropenia varies depending on factors such as type and extent of malignancy, intensity of chemotherapy, and receipt of prophylactic granulocyte colony-stimulating factor, and the incidence can range from 10% to 60%.^{23,25,153} The incidence of fever and neutropenia can increase to 70% to 100% in patients receiving particularly intensive and myelosuppressive chemotherapy.¹⁵⁷

Bacterial Pathogens

Fever in the setting of neutropenia is often the initial and potentially the only clinical sign of a bacterial, fungal, or viral infection. Of patients in whom a pathogen is identified, bacteria predominate. In a landmark study evaluating 793 pediatric cancer patients with fever and neutropenia, Pizzo et al. found that 87% of patients with a microbiologically documented infection had a bacterial pathogen identified.¹²⁴ Recent epidemiologic studies specific to pediatric fever and neutropenia have suggested a reduction in the proportion of episodes that are attributable to bacteria. However, despite the reduction, bacterial pathogens still accounted for the majority of all identified pathogens.^{23,63}

Early reports on the epidemiology of these bacterial infections highlighted gram-negative pathogens as the predominant cause of infection in neutropenic children and adults. *Escherichia coli*, *Pseudomonas*

TABLE 68.1 Distribution of Bacterial Pathogens in Selected Pediatric Fever and Neutropenia Cohorts

	Ariffin ¹² (2002)	Lehrnbecher ⁹² (2004)	Castagnola ²³ (2007)	Hakim ⁶³ (2009)	Gupta ⁶⁰ (2011)
Study location	Malaysia	Germany	Italy	United States	El Salvador
Patient type	Any malignancy	Acute myeloid leukemia	Leukemia, solid tumor, or allogeneic HSCT	Any malignancy	Any malignancy
Clinical scenario	Fever and neutropenia	Fever with and without neutropenia	Fever and neutropenia	Fever and neutropenia	Fever and neutropenia
Infection episodes (total patients)	762 (513)	855 (304)	614 (NA)	337 (337)	106 (86)

^bIncludes polymicrobial infections.

aeruginosa, and *Klebsiella* spp. were the three most commonly isolated pathogens.¹⁴⁶ Subsequently, towards the end of the 1980s, gram-positive pathogens were being increasingly recognized as an important source of fever of neutropenia,^{41,167} and, soon thereafter, gram-positive pathogens were found to be more common than gram-negative organisms.¹⁷⁵ This shift in pathogens has been attributed to increased use of central venous lines, a greater prevalence of mucositis, and prophylactic regimens with predominantly gram-negative activity. Additionally, escalation to more intensive chemotherapy regimens, such as those containing high-dose cytarabine, have resulted in more impressive mucositis, which has contributed to increases in specific pathogens such as viridans group streptococci.¹⁵²

The spectrum of bacterial pathogens will depend on specific chemotherapy, use of antimicrobial prophylaxis, and setting. Table 68.1 displays the distribution of bacterial infections across various international pediatric oncology cohorts.^{12,23,60,63,92} Variation in the frequency in isolation of a bacterial pathogen across cohorts is apparent. This is likely secondary to variation in geographic location, composition of each cohort, diagnostic testing practices, and prophylactic antimicrobial regimens. With the exception of the Malaysian cohort, the predominance of gram-positive pathogens has persisted in pediatric oncology cohorts, consistent with data published toward the end of the previous century. Among the gram-positive pathogens viridans group streptococci, *Staphylococcus aureus*, and coagulase-negative staphylococci are predominant. *E. coli*, *P. aeruginosa*, and *Klebsiella* spp. remain the most commonly identified gram-negative pathogens.^{12,23,60,63,92}

Fungal Pathogens

As discussed in more detail later, the likelihood of invasive fungal disease (IFD) during an episode of fever and neutropenia varies depending on a number of risk factors. Generally fungal pathogens are considered as the etiology of fever and neutropenia when these two clinical signs are concurrently prolonged or when fever is recurrent during the same episode of neutropenia in the setting of broad-spectrum antibiotic therapy. Defining the epidemiology of IFD in specific patient populations can be challenging. Published consensus criteria for defining the presence of IFD have been helpful in standardizing reporting of such infections.⁴⁰ However, limitations in diagnostic modalities for identifying an IFD persist and thus published IFD rates are likely underestimated. Despite these challenges, prospective multicenter data have documented a proven or probable IFD rate ranging from 3% to 5% of children hospitalized with fever and neutropenia.^{80,113,166} *Candida* spp. are the most commonly isolated fungal pathogens, likely related to the frequent existence of *Candida* as a commensal organism on the skin and mucosal surfaces.⁴⁸ Compromise of these important anatomical barriers (e.g., mucositis) can result in invasive candidiasis. Additionally *Candida* spp. can infect central venous catheters, which are commonly present in

children with cancer. Although mortality data specific to candidiasis in pediatric oncology patients are limited, the attributable mortality of invasive candidiasis in all pediatric patients has been estimated to be 10%.¹⁷³

Invasive mold disease (IMD) is less common but an extremely important complication of neutropenia, given the poor outcomes related to these pathogens. In two contemporary pediatric cases series, only 54% to 60% of patients with IMD responded to therapy in the first 12 weeks from diagnosis, and approximately 30% of patients diagnosed with an IMD died within the same time period.^{56,169} Among the mold pathogens, *Aspergillus* spp. are most common, followed by organisms of the Mucorales order.^{56,152,169}

Viral Pathogens

Owing to advancement in viral diagnostic methodologies, multiple publications have attempted to delineate the attribution of fever and neutropenia events to viral pathogens. Table 68.2 displays the frequency of recovered viral upper respiratory pathogens in pediatric patients presenting with fever, with or without symptoms of a viral infection.^{15,30,84,94,158} Although only Torres et al. was limited to episodes of fever and neutropenia, the majority of patients in the other cohorts had fever and neutropenia at the time of their evaluation. The frequency of laboratory-confirmed viral respiratory infection ranged from 8% to 59%. A more recent publication using administrative data from the Kid's Inpatient Database suggested that up to 12.1% of fever and neutropenia episodes are the result of viral infection. However, in this study, the identification of fever and neutropenia admissions and presence of viral infection were dependent on ICD-9 discharge diagnosis codes.¹⁰⁷ These codes have not been validated for either fever and neutropenia or viral infection, and thus it is difficult to ascertain the accuracy of these findings.

Although some authors have suggested routine comprehensive viral testing at the time of presentation,^{30,158} the utility of routine viral testing is not clear. First, ideally, the identification of a viral pathogen should allow for discontinuation of broad-spectrum antibiotics in the febrile and neutropenic patient. However, bacterial and viral infections are not mutually exclusive, with as many as 13% to 33% of patients with a viral pathogen suffering a simultaneous sterile site bacterial infection.^{84,158} Second, the evolution in the availability of viral PCR testing may result in detection of virus well after clinical resolution. Finally, only a few antiviral agents are available for the treatment of some of these viral pathogens, and their effectiveness is not clearly delineated. Viral testing should be limited to patients in whom positive results would effect a change in management, such as deescalation of antibiotic therapy, initiation of an appropriate antiviral therapy (e.g., neuraminidase inhibitor for influenza), or institution of appropriate isolation precautions.

TABLE 68.2 Frequency of Viral Respiratory Pathogens at Presentation for Fever and Neutropenia

	Long ⁹⁴ (1987)	Arola ¹⁴ (1995)	Christensen ³⁰ (2005)	Koskenvuo ⁸⁴ (2008)	Torres ¹⁵⁸ (2012)

FEVER AND NEUTROPENIA OF UNKNOWN ORIGIN

Despite evaluation, many patients have negative cultures and do not have a clinically evident site of infection. This presentation is often referred to as fever of unknown origin (FUO). Although children with FUO can have an occult infection, an infectious pathogen or clinical infection is not detected. In a combined pediatric and young adult cohort, Pizzo et al.¹²³ described 306 consecutive episodes of fever and neutropenia in patients cared for at the National Institute of Health. They found that only 54% of patients had an identifiable infection within 7 days from presentation. Despite advances in infectious diagnostic modalities (i.e., improved blood culture mechanisms, sensitive viral tests), the rates of unidentified etiology of fever and neutropenia in children have remained high, ranging from 33% to 79%.^{12,23,63,92,158}

RISK STRATIFICATION

Risk Stratification at Initial Presentation

The risk of infection and serious morbidity is highly heterogeneous among patients with fever and neutropenia, and this heterogeneity has resulted in efforts to risk stratify patients. Most of the efforts in risk stratification have been directed toward identifying patients at low risk of bacteremia and adverse outcomes who may be managed with less aggressive interventions such as outpatient management, early discontinuation of antibiotics, or oral therapy. Some studies have focused on identifying high-risk patients to facilitate intensification of diagnostic investigation, empiric therapy, or monitoring. In adults, the predominant risk stratification schema that has emerged is the Multinational Association for Supportive Care in Cancer (MASCC) Scoring System. Unfortunately this system incorporates parameters that are not applicable to children, such as lack of chronic obstructive pulmonary disease and age less than 60 years, to determine low-risk status. The inclusion of these parameters limits the applicability of this scoring system to children.¹⁵⁴

A number of both retrospective and prospective pediatric cohort studies have been performed to evaluate various clinical prediction rules for designating children as low-risk for infection in the setting of fever and neutropenia. These studies have been summarized in multiple meta-analyses.^{62,120,118} Considered collectively, data from these studies support the potential success of implementing a risk stratification protocol. However, each trial used varied patient-relevant factors (e.g., age, malignancy), clinical factors (e.g., timing of chemotherapy, degree of fever, presence of hypotension), and laboratory parameters (e.g., duration and depth of neutropenia, C-reactive protein value, platelet count) and had various outcome definitions (e.g., bacteremia, serious infection, death). Furthermore attempts to validate six of the pediatric risk stratification schemas in separate populations have resulted in suboptimal performance compared to the original study.* A primary

reason for suboptimal performance during validation is variation in the clinical setting between the derivation and validation cohorts. Currently centers applying a risk prediction model for children with fever and neutropenia should identify a model that is most consistent with their patient population (rules tend to perform less favorably when applied in different settings) and their local clinical practice and is most feasible to implement. Additionally, at the time of implementing a risk stratification protocol, a center should clearly delineate the goals of its risk stratification. This articulation should include a framework on how the risk stratification will inform clinical decision-making (i.e., low-risk patients can be discharged to home with outpatient follow-up). The framework should be developed by a multidisciplinary team and clearly communicated to both health care providers and patients and their families.

More recently an individual patient data meta-analysis inclusive of data from 22 datasets representing previous cohorts of children with fever and neutropenia was performed as part of a global collaboration called Predicting Infectious Complications in Children with Cancer (PICNICC).¹¹⁹ The analysis considered demographic, clinical, and laboratory results in deriving a risk prediction model for likelihood of microbiologically defined infection in children with fever and neutropenia. The final model included malignancy type, temperature, clinical appearance of the child, hemoglobin level, total white blood cell count, and absolute monocyte count. The resultant prediction rates for microbiological infection closely correlated with actual estimates, and the model was robust to internal validation. Because the data that informed this model derivation were assembled from cohorts across various clinical settings, it represents a potential tool to be leveraged in various fever and neutropenia settings. Prior to widespread application, it needs to be validated externally.

As biomarkers continue to be discovered, there is always the potential to improve on current prediction rules. Investigators have studied the clinical utility of more than 170 different biomarkers, including cytokines, cell surface markers, coagulation system molecules, receptors in various inflammatory cascades, and acute phase reactants in various pediatric and adult clinical settings.¹²¹ A number of biomarkers have emerged as potentially useful tools to guide approaches for fever and neutropenia, some of which have already been used in the aforementioned prediction rules. However, although some biomarkers are often elevated in patients with a bacterial infection, an inability to identify a threshold value for a single biomarker to accurately discriminate between infected and uninfected patients has limited their clinical applicability. Future investigations that incorporate multiple biomarkers with traditional laboratory values and clinical findings may improve the discriminating ability of a pediatric risk prediction rule.

Risk Stratification for Invasive Fungal Disease

The risk stratification prediction rules just discussed are typically relevant to risk for microbiologically documented infections at the time of presentation for fever and neutropenia. However, concern for an IFD

*References 5, 7, 8, 16, 78, 95, 96, 106, 120, 118, 128, 134, 137, 138.

is often increased when fever and neutropenia persist despite initial empiric antibiotic therapy. Unlike the risk for microbiologically documented infection at presentation, there have been no pediatric studies dedicated to deriving an IFD risk prediction rule in children with persistent fever and neutropenia. However, a number of observational studies have identified important factors that are associated with an increased risk for IFD.

Patient populations with reported IFD incidence greater than 10% include children with acute myeloid leukemia (AML),^{59,151,152} relapsed acute lymphoblastic leukemia (ALL),⁸⁷ and recipients of an allogeneic stem cell transplantation.^{17,47,67,82,162} Additionally increasing duration of neutropenia is a commonly identified risk factor for IFD.^{47,67,72,85,170} The exact duration at which the risk significantly increases is not definitively known but observational data in children with AML suggest it is somewhere between 10 and 15 days of neutropenia.⁷² Depth of neutropenia is also an important component of the neutropenia risk profile for IFD. An absolute neutrophil count (ANC) of less than 100/ μ L or an absolute monocyte count (AMC) of less than 100/ μ L during an episode of fever and neutropenia was each associated with an increased risk of IFD.^{103,166} Exposure to high-dose steroids and/or prolonged steroid exposure (>10 days) have also been identified as a risk factor for IFD.^{47,58,66,67,72,85,103} Finally increasing age has been associated with increasing risk for IFD. Age thresholds of 7.5 years¹⁴⁰ and 10 years^{47,70,152} have been suggested for dichotomizing IFD risk by age. However, an optimal threshold for categorizing age related to IFD risk is unclear.

Based on these data, pediatric fever and neutropenia guidelines⁹⁰ recommend that patients with fever and neutropenia should be considered IFD high risk if they have recently received intensive chemotherapy (e.g., AML or relapsed ALL patient) with expected prolonged neutropenia and/or recent exposure to prolonged courses of steroids. This stratification for identification of IFD high-risk patients is a general guide, and it should be noted that IFD has been described in patients who would not meet this high-risk classification.⁴⁶ Additional work is necessary to establish specific prediction rules to incorporate multiple risk factors into a single risk prediction rule to more accurately discriminate between IFD high- and low-risk patients.

HISTORY AND PHYSICAL EXAM

Prior to initiating routine diagnostic testing, a complete history and physical exam should be performed. A comprehensive history can identify important exposures that could alert the physician to consider less common opportunistic infections and direct early additional diagnostic testing. The history should include details about symptoms other than fever, adherence to current medications (especially prophylactic antimicrobials), and most recent chemotherapy regimen. Additionally the clinician should ask about sick contacts at home, updates on recent travel, daycare/school/occupational exposures, animal exposures (e.g., new pets such as cats or birds, or contact with farm or wild animals), and dietary exposures (e.g., unpasteurized cheeses). A thorough history of prior dwelling locations is becoming increasingly important among pediatric oncology patients in the evolving era of country-to-country transfers. Knowledge on prior living locations may have an impact on a patient's risk for multidrug-resistant pathogens¹¹⁰ and help to identify potential dietary or environmental exposures that predispose patients to rarely seen pathogens. On physical exam, specific attention should be focused on areas sometimes overlooked, such as the naso- and oropharynx, middle ears, genitalia, perineum (in particular, the perianal area), and scalp. Central venous line exit sites are also important areas for inspection.

INITIAL DIAGNOSTIC EVALUATION

Regardless of the risk designation of a pediatric patient presenting with fever and neutropenia, an infectious diagnostic evaluation is warranted in all such patients. Various testing modalities may be employed depending on the status of the presenting patient. In all patients, routine blood cultures should be performed prior to initiation of antibiotics. Because most patients have central venous access, this would include culturing all lumens of the central venous catheter.

Performing a peripheral blood culture in addition to central venous cultures is controversial. Multiple studies of paired cultures taken from pediatric and adult patients with underlying malignancy suggest a small but consistent probability of detecting true bacteremia from the peripheral culture when the central culture is negative.^{1,27,43,127,141} A meta-analysis determined that 13% of bacteremias were only identified with a peripheral culture.¹³³ These data suggest that a peripheral blood collection should be considered concurrent with cultures from the central line to optimize detection of a causative pathogen for the fever and neutropenia episode.

The yield of repeated daily blood cultures after the initial evaluation is low. In a series of 193 consecutive fever and neutropenia episodes in 117 pediatric patients, 95 of the episodes revealed that the index culture was negative and the fever and neutropenia persisted.¹¹¹ Among these 95 episodes, 421 additional blood cultures were obtained in the ensuing 2 weeks. Only 4 of the 421 additional blood cultures were positive for a bacterial pathogen. Given the low yield of subsequent blood cultures in the setting of persistent fever and neutropenia with an initial negative culture, it is reasonable to follow the adult guideline recommendations, which suggest daily blood cultures for only the first 3 days of fever and neutropenia.⁵⁴ Any additional blood cultures should be reserved for patients with a significant clinical change (e.g., hypotension, tachypnea) or in those whose fever initially resolved but then recurred.

A urine culture is warranted if the patient presents with signs or symptoms of a urinary tract infection (UTI). The importance of routine urine cultures for children presenting with fever and neutropenia without signs or symptoms of a UTI is controversial. In a typical pediatric population, UTI is a common source of FUO.²⁹ Asymptomatic UTIs are likely to be more common in neutropenic children given the lack of an appropriate inflammatory response. This is evidenced by the fact that only 4% of oncology patients with a urine culture yielding a UTI pathogen will have pyuria on urinalysis.⁷⁹

A number of observational studies have evaluated the yield of urine cultures in pediatric patients presenting with fever and neutropenia. Hakim et al. noted that of 337 patients presenting with fever and neutropenia 2 (0.6%) had a positive urine culture.⁶³ Data from Santolaya et al. revealed the presence of a urinary pathogen in 4.6% of fever and neutropenia episodes.¹³⁷ Urine culture was not a component of the routine diagnostic evaluation in either study, so it is possible that there were more patients with a UTI that went undetected. When urine culture is routinely performed in children presenting with fever and neutropenia, the frequency of a UTI is reported to be 8.6%.¹³⁵

Given these data, urine culture in patients presenting with fever and neutropenia should be obtained if a mid-stream or clean catch specimen is feasible. In patients who require urinary catheterization for specimen collection, the risks of the intervention should be weighed against the benefit of potentially identifying the source of the fever. However, antibiotic administration should never be delayed if a patient is unable to provide a timely urine specimen.

In children presenting with focal respiratory signs (e.g., tachypnea or auscultatory changes) or symptoms (e.g., cough or increased work of breathing), chest radiography should be a component of the initial diagnostic workup. Additionally, in children with respiratory symptoms who are capable of producing an adequate sputum sample, the clinician should consider sputum collection for culture. The utility of chest radiography has been examined in children presenting with fever and neutropenia without respiratory symptoms. Together these studies evaluated 487 episodes of pediatric fever and neutropenia; only five chest radiographs revealed pneumonia in the absence of any respiratory signs or symptoms.^{51,76,83,131} These data do not support the routine use of chest radiography in children with fever and neutropenia in the absence of signs or symptoms of respiratory issues.

Finally important findings noted on history and/or physical exam should dictate additional testing for less common sources of infection. For instance a patient presenting with fever and neutropenia and a reported history of a lovebird in the home should prompt additional testing for cryptococcosis early in the evaluation period.¹⁶¹ Likewise identification of black cutaneous lesion(s) in a patient with antecedent neutropenia should prompt consideration for immediate biopsy to determine if the lesion represents a cutaneous mold infection. In the

setting of exotic exposures or important clinical findings, consultation with an infectious disease physician with experience in immunocompromised patients may be warranted early in the hospitalization because early identification of less common opportunistic infections will likely translate into improved patient care.

INITIAL THERAPY FOR FEVER AND NEUTROPENIA

Traditionally the standard of care for fever and neutropenia has been hospital admission with administration of intravenous broad-spectrum antibiotics. However, employing a risk stratification rule (as discussed in the previous Risk Stratification section) offers the opportunity to differentially manage children at low risk of having bacteremia or an adverse outcome at the time of presentation for fever and neutropenia. Low-risk patients may be managed with oral antibiotics if oral therapy is feasible (e.g., absence of vomiting and malabsorption) in the inpatient or outpatient setting. If the hospital infrastructure supports an ambulatory approach, then patients may be treated as outpatients with oral or intravenous therapy.^{99,132,156} Those who are not identified as low risk should be admitted for initiation of a parenteral antibiotic regimen with broad-spectrum gram-negative coverage, including *P. aeruginosa* and gram-positive coverage for organisms such as the viridans group streptococci. Antibiotic options that meet these criteria include an anti-pseudomonal penicillin (e.g., piperacillin-tazobactam), a cephalosporin (e.g., cefepime), or a carbapenem (e.g., meropenem or imipenem). Two separate pediatric meta-analyses compared anti-pseudomonal penicillins to cephalosporins,¹⁰⁰ as well as anti-pseudomonal penicillins to carbapenems,¹⁰¹ and concluded similar effectiveness of each of these options for empiric therapy.

It is important to note that a meta-analysis of predominantly adult randomized controlled trials (RCTs) identified a significant increased risk for all-cause mortality in patients receiving cefepime compared to those receiving other β -lactam agents for fever and neutropenia.^{116,172} However, in a subsequent analysis, the US Food and Drug Administration (FDA) supplemented the available published data with unpublished mortality data specific to febrile neutropenic patients and found no mortality difference between the antibiotic options. Importantly the FDA specifically reviewed the available case report forms from the fever and neutropenia trials and could not identify a biologically plausible reason for the previously identified association between cefepime and death.⁷⁷ An additional meta-analysis of fever and neutropenia trials, as well as a retrospective investigation of pediatric AML patients, did not reveal a difference in mortality risk between those exposed to cefepime compared to other antibiotics commonly used for fever and neutropenia.^{52,159} Evaluating the available data, cefepime should remain as a viable option for empiric therapy for febrile neutropenia.

In general, for a child presenting with fever and neutropenia that is otherwise stable, monotherapy with an antipseudomonal penicillin, an antipseudomonal fourth-generation cephalosporin, or an antipseudomonal carbapenem is appropriate. An empiric monotherapy regimen is supported by data from recent meta-analyses in pediatric fever and neutropenia that all found no statistically significant differences in treatment failure, infection-related mortality, or overall mortality when comparing monotherapy with combination regimens.¹⁰⁰ Both the current pediatric⁹⁰ and adult⁵⁴ fever and neutropenia guidelines support empiric anti-pseudomonal monotherapy.

Because gram-positive organisms are an increasing cause of fever and neutropenia episodes, the utility of adding additional broad gram-positive coverage (e.g., vancomycin) to the empiric regimen has been questioned. Although pediatric-specific data do not exist, multiple adult RCTs have investigated the efficacy of adding a glycopeptide to various β -lactam-containing regimens. These trials were summarized in two separate meta-analyses, each of which failed to identify a significant benefit relative to all-cause mortality in patients receiving empiric glycopeptide therapy.^{115,164} Therefore routine empiric glycopeptides are not recommended for fever and neutropenia.

As suggested by the adult and pediatric fever and neutropenia guidelines,^{54,90} certain patient-specific factors should be evaluated when managing antibiotic regimens. For instance, in patients presenting or

developing hemodynamic instability, broadening the coverage to include resistant gram-negative and -positive organisms, such as the addition of a second gram-negative agent (e.g., an aminoglycoside) and vancomycin, is important. Additionally broad gram-positive therapy should be considered in patients with evidence of a focal gram-positive infection (e.g., cellulitis or central access tunnel infection). Finally a history of an invasive infection with a resistance organism (e.g., methicillin-resistant *S. aureus* [MRSA]) should inform empiric antibiotic choices during subsequent fever and neutropenia episodes.

These recommendations for empiric antibiotic coverage should be considered guiding principles rather than dictums. Each center's local empiric antibiotic regimen should be customized based on information regarding pathogen resistance from the institution's antibiogram that is specific to the oncology patient population. For example, viridans group streptococci are a common group of pathogens that result in bacteremia and sepsis in AML patients. The resistance profile of these organisms is variable over time and by institution. A center may have elevated MRSA rates, and thus vancomycin would be a reasonable component to the empiric therapy regimen for fever and neutropenia until at least the initial blood culture results are available. The threshold of resistance that would trigger a change in the locally recommended empiric therapy regimen is not known. Such decisions regarding empiric regimen changes should be made with input from oncologists, infectious disease specialists, microbiologists, and pharmacists.

For low-risk patients, outpatient management with either oral or parenteral therapy for fever and neutropenia has garnered much support in recent years. A number of pediatric-specific randomized trials have noted similar safety for early hospital discharge on intravenous therapy versus continued hospitalization,^{3,136} early hospital discharge on oral therapy versus continued hospitalization,¹⁹ inpatient intravenous versus inpatient oral therapy,²¹ and outpatient intravenous versus outpatient oral therapy.^{61,109,114,117} Although each of these studies was limited by small sample sizes, a pediatric-stratified analysis of randomized trials and a pediatric-specific meta-analysis of prospective studies support the safety of outpatient management and oral antibiotic administration in low-risk children with fever and neutropenia.^{100,132,156} In addition, outpatient management of low-risk febrile neutropenic patients is associated with a large reduction in health care costs compared with inpatient management.^{136,156} Patients and parents both report that the home environment has a positive impact on physical activity, self-esteem, and family activities.¹⁴⁹ However, the acceptance of an outpatient management plan by patients and their caregivers is limited by the perception of reduced effectiveness of outpatient management^{19,45,126} and the potential burden of outpatient care.¹⁵⁰ In a discrete choice experiment, Sung et al. found that an outpatient management plan that required three times a week clinic visits or a risk for readmission that was 7.5% or greater would not be tolerable to patients and families. These data highlight that as the standard of care for low-risk fever and neutropenia transitions from the inpatient to outpatient setting, it will be necessary to include families and patients in care decisions.

DIAGNOSTIC EVALUATION FOR PERSISTENT FEVER AND NEUTROPENIA

A primary concern in the patient with persistent fever and neutropenia despite broad-spectrum antibiotics is the possibility of an IFD, especially in those patients considered to be at high risk for IFD. There are often no specific clinical signs to suggest an IFD diagnosis, yield of routine blood cultures for yeasts such as *Candida* species ranges between 40% and 60%, and such cultures are not capable of reliably detecting some molds such as *Aspergillus* spp.¹¹ Thus there has been an increased focus on improving diagnostic modalities for detecting IFD in these patients. Two serum fungal biomarkers have received significant attention, galactomannan (GM) and β -D-glucan (BG).

The GM assay, developed to detect a cell wall component of *Aspergillus* spp., has been evaluated in a number of cohorts of patients with persistent fever and neutropenia.^{13,24,28,37,44,49,71,130} Each of these cohorts had a different invasive aspergillosis incidence (i.e., pretest probability) ranging from 0% to 31%. The positive predictive value (i.e., posttest probability) from these cohorts ranged from 0% to 100%. In some reports the GM

resulted in an improvement of pretest probability from approximately 4% to a posttest probability of greater than 70%.^{13,24} Unfortunately, in other reports, the results of the GM assay added little diagnostic benefit over the pretest probability.^{28,44,49,71,130} Interpreting the publications collectively, it is difficult to endorse routine use of the GM assay during periods of persistent fever and neutropenia. Clinicians should compare characteristics of their patient population to the cohorts studied in the aforementioned publications. If their patient population is similar to one of the cohorts in which the GM provided reasonable diagnostic improvement from pretest to posttest probability, then it would be reasonable to consider employing the GM assay as a diagnostic tool during fever and neutropenia. The other major limitation of GM is that it does not detect non-*Aspergillus* molds and thus comfort with discontinuation of mold-active antifungal therapy will vary depending on local epidemiology and provider preferences. Ultimately, prior to ordering a GM assay, a clinician needs to ask how a positive or negative result would change the provision of clinical care for the patient being tested.

The BG assay has the potential to detect a wide variety of invasive fungal pathogens with the exception of *Cryptococcus* and molds of the Mucorales order. This assay has been evaluated in three pediatric studies,^{14,81,174} only one of which was exclusive to pediatric patients with persistent fever and neutropenia.¹⁷⁴ In this setting, the sensitivity and specificity of the BG assay were 82% with a resultant posttest probability of 49% in a cohort having a pretest probability of 16.9%.¹⁷⁴ It is difficult to extrapolate these results to populations in the United States because the assay used by the investigators is not the same as the assay commercially available in the United States. At this time, there are not enough data to support the routine use of the BG assay in children with persistent fever and neutropenia.

Polymerase chain reaction (PCR) testing represents another potential adjunctive diagnostic tool to detect an IFD. Both pan-fungal PCR and *Aspergillus*-specific PCR have been assessed in pediatric patients with fever and neutropenia. Similar to the GM assay, some of the reports suggest a reasonable improvement from pretest to posttest probability of disease,^{48,93} whereas other studies showed little diagnostic benefit of a positive test relative to the pretest probability of an IFD.^{26,42,69,86,98,130} As noted for the GM assay, these collective findings do not allow for an endorsement of routine fungal PCR analyses in children with fever and neutropenia.

Last, radiographic testing, such as systematic computed tomography (CT) imaging, has been proposed as a method to detect an infectious etiology of persistent fever and neutropenia. Evaluation of adult patients early in the course of prolonged fever and neutropenia suggested that a high-resolution CT scan of the chest with subsequent diagnostic intervention (e.g., bronchoalveolar lavage) has the potential to direct additional specific antimicrobial therapy⁶⁴ and to reduce the time to diagnosis of invasive pulmonary aspergillosis.²² Pediatric data on the utility of systematic CT imaging of the sinuses, chest, abdomen, and pelvis in prolonged fever and neutropenia was assessed in a retrospective case series of 68 pediatric episodes. Only chest CT imaging provided clinically useful information resulting in an altered course of therapy in two patients.² A pilot study of a rapid protocol for magnetic resonance imaging (MRI) of the lung found comparable results of this modality to high-resolution CT scan.¹⁴⁸ However, the study size was too small to assess the impact of this modality on informing clinical decision making.

Regardless of the diagnostic modality, the challenge with interpreting the data on these adjunctive tools in the setting of prolonged fever and neutropenia is that, in previous studies, significant variation existed relative to patient populations, interpretations of positive assay threshold, type of test used, timing and frequency of testing, and definitions for IFD. It appears that no single diagnostic modality has proved ideal for directing the care of the pediatric patient with prolonged fever and neutropenia. It may be that a combination of diagnostic tests is necessary to best inform clinical practices. In an adult RCT, a preemptive antifungal therapy approach guided by clinical assessment, laboratory testing (e.g., GM testing), and chest imaging results was shown to be as effective as empiric antifungal therapy.⁵³ Future studies are necessary to confirm this as an appropriate approach for prolonged fever and neutropenia in children.

THERAPEUTIC ADJUSTMENTS FOR PROLONGED FEVER AND NEUTROPENIA

Adjustment of Empiric Antibiotic Therapy

There are few data to guide recommendations for adjusting antibiotic therapy in patients with prolonged fever and neutropenia with or without an identified source. One adult RCT found that the addition of vancomycin in patients with persistent fever and neutropenia receiving piperacillin-tazobactam monotherapy failed to provide benefit relative to fever resolution.³² Both adult and pediatric guidelines agree that the persistence of fever alone is not an indication for expanding or modifying antibiotic coverage, assuming the patient remains clinically stable. In this setting, close monitoring is necessary to evaluate for changes in clinical status.^{53,89} Signs of clinical deterioration (e.g., hypotension or respiratory distress) should prompt broadening of the antimicrobial regimen. The nature of the clinical change should dictate the specific addition or modification to the antimicrobial regimen.

An important question is the optimal time to discontinue antibiotics when fever has resolved and no pathogen has been identified. Retrospective^{9,10,74,91} and prospective observational^{131,108} and randomized¹³⁹ studies support the safety of antibiotic cessation after fever resolution with evidence of bone marrow recovery. However, there are limited data on stopping antibiotics prior to evidence of bone marrow recovery. In two small randomized trials of patients meeting low-risk criteria, there was no differences in the recurrence of symptoms for infection in patients continued on antibiotic therapy until neutrophil recovery versus cessation of empiric antibiotics.^{78,139} However, in high-risk patients, cessation of antibiotics may be associated with worse outcomes. Pizzo et al. showed that if empiric antibiotics are stopped at 7 days in patients with resolution of fever but persistent neutropenia, there is a significant risk for return of fever and potential for death.¹²⁵ More recently, Micol et al. observed the outcomes of adults with AML and fever and neutropenia where antibiotics were discontinued after fever resolution.¹⁰⁵ The study was stopped after seven patients because three patients had return of fever, two had documented bacteremia, and one required intensive care monitoring. Future research is needed to compare the effectiveness of stopping antibiotics versus continuing until neutrophil recovery in both low- and high-risk populations.

In patients in whom there is documentation of an organism believed to be the source of fever, the antimicrobial regimen should be modified to target the identified organism. It is not clear whether it is necessary to retain broad-spectrum coverage appropriate for initial presentation of fever and neutropenia or whether it is possible to narrow the antibiotic regimen to the pathogen isolated while the patient is still neutropenic. Interestingly, 6% of pediatric AML patients will develop a secondary bacteremia despite continued antibiotic therapy for a bacteremia event presenting earlier in the neutropenic period.¹⁶⁰ Notably the second bacteremia events presented despite continued broad-spectrum antibiotic therapy. In the absence of definitive data, a reasonable approach would be to maintain broad-spectrum coverage if empiric therapy would otherwise be continued and to narrow therapy if criteria for cessation of empiric therapy are met. Future investigation of narrowing therapy in patients with an identified pathogen and clinical improvement but persistent neutropenia is necessary to determine whether this approach is safe.

Initiation of Antifungal Therapy

Initial prospective randomized data highlighted the success of empiric antifungal therapy in children with persistent fever and neutropenia despite broad-spectrum antibiotics.¹²² As previously discussed, a number of publications have focused on identifying factors to assess risk for IFD and to leverage these risk factors to guide empiric antifungal therapy decisions. Current adult guidelines support the initiation of empiric antimold therapy in patients with persistent or recurrent fever lasting 4 to 7 days when the duration of neutropenia is anticipated to persist beyond 7 days.⁵³ Similarly the pediatric-specific guidelines have supported the initiation of empiric antifungal therapy patients after 96 hours of fever and neutropenia that is not responsive to broad-spectrum antibiotics when one of the following criteria are met: the duration of neutropenia

is anticipated to last longer than 10 days; the patient has underlying AML, relapsed ALL, or is an allogeneic hematopoietic stem cell transplant (HSCT) recipient; or the patient has been exposed to high-dose steroids.⁸⁹ In patients not meeting one of these high-risk IFD criterion, it is reasonable to withhold empiric antimold therapy.

When initiating an empiric antimold agent, options include an amphotericin B product (amphotericin B deoxycholate, lipid complex amphotericin B, or liposomal amphotericin B), an echinocandin (anidulafungin, caspofungin, or micafungin), or an extended-spectrum azole (voriconazole or posaconazole). Pediatric prospective randomized trials have compared caspofungin to liposomal amphotericin B⁹⁷ and the latter to amphotericin B deoxycholate.¹²⁵ Although similar relative to efficacy outcomes, there were significantly fewer side effects associated with liposomal amphotericin B as compared to amphotericin B deoxycholate. Safety and efficacy comparisons showed no difference between caspofungin and liposomal amphotericin. Given these data, caspofungin or liposomal amphotericin are both appropriate first-line agents for empiric antifungal therapy. Second-generation triazoles represent alternative options for empiric mold therapy. However, the lack of pediatric-specific data for these agents limits the feasibility of their use. While voriconazole dosing recommendations are available for children 2 years of age and older, there is significant intra- and interpatient variability in voriconazole pharmacokinetics among the pediatric population.^{75,144} Dosing recommendations for posaconazole do not exist for those younger than 13 years of age, and there are no pediatric dosing recommendations for isavuconazole. Finally, none of these azoles has been specifically studied as an empiric antimold therapeutic agent in children.

The empiric antifungal therapy approach for prolonged fever and neutropenia has been challenged because of the lack of specificity of prolonged fever and neutropenia as a marker for IFD, the potential to unnecessarily expose patients to toxicities associated with antifungal agents, and the increased costs in administering these agents for prolonged periods.^{39,102} Although designation of high- and low-risk IFD status has reduced some unnecessary empiric therapy, it has not eliminated it. As noted previously, an alternate approach to empiric antifungal therapy is a preemptive strategy. In this approach, the results of a combination of adjunctive diagnostic studies (e.g., fungal biomarkers and CT scans) are utilized to inform the initiation of antifungal therapy. A retrospective analysis suggested that a preemptive approach in adult allogeneic HSCT recipients was feasible and had the potential to reduce antimold therapy exposure.¹¹² In an ensuing randomized trial of high-risk adult fever and neutropenia patients, Cordonnier et al. showed that a preemptive approach reduced the cost associated with antifungal therapy without a change in mortality. However, the preemptive approach was associated with a higher IFD rate.³³ Further refinement of a preemptive approach with a focus on pediatric cohorts is necessary before such a strategy can be adopted in children.

The appropriate time to discontinue empiric antifungal therapy has not been well defined. A conservative approach is to continue until resolution of neutropenia; this approach is supported by a recently published pediatric guideline, but in the absence of pediatric specific data.⁸⁹ Some clinicians perform CT scans at the time of neutropenia resolution and use this information to inform cessation of antifungal therapy. However, there are no data to document the clinical impact of this approach. Future research should focus on identifying the optimal criteria for cessation of antifungal treatment in the empiric setting.

PREVENTION MEASURES

Antibacterial Prophylaxis

Much effort has focused on determining the efficacy and safety of antibacterial prophylaxis in patients with cancer. In 2005, two large randomized placebo-controlled trials evaluated the efficacy of levofloxacin for preventing fever in patients with anticipated short and long periods of neutropenia.^{20,36} These trials discovered that levofloxacin prophylaxis reduced the rates of fever and bacteremia during periods of anticipated prolonged neutropenia²⁰ and similarly reduced the rate of fever and infection during anticipated short periods of neutropenia.³⁶ Furthermore a meta-analysis of 95 randomized trials revealed a significant reduction

in mortality when antibiotic prophylaxis was administered to neutropenic patients.⁵⁵ Based on these data, multiple adult guidelines support the use of fluoroquinolone prophylaxis.^{53,88} However, the limited pediatric data regarding the utility of antibacterial prophylaxis⁴ have precluded a similar pediatric recommendation. Furthermore potential negative consequences associated with prophylaxis, such as an increase in resistance among colonizing organisms or association with *Clostridium difficile* infection or IFD, were not adequately evaluated in the aforementioned large adult trials. Currently the Children's Oncology Group is conducting a trial to investigate the benefits of levofloxacin prophylaxis in high-risk children with neutropenia and intends to evaluate some of these important secondary outcomes.

Antifungal Prophylaxis

Prophylactic antifungal therapy has also been explored as a mechanism to reduce IFD in patients with neutropenia. The earliest adult trials showed fluconazole was efficacious as compared to placebo in reducing systemic and superficial fungal infections in bone marrow transplant recipients.^{57,147} A subsequent meta-analysis suggested that the benefit of prophylactic fluconazole was realized in the setting of increased risk (>15%) for systemic fungal infection.⁷³ This meta-analysis appropriately highlighted the need to consider the prevalence of IFD when considering the impact of antifungal prophylaxis in a specific patient population. More recently, agents with anti-mold activity have been evaluated in the prophylactic setting. Vehreschild et al. showed, in a small cohort of adult AML patients, that voriconazole as compared to placebo was efficacious in reducing the rate of pulmonary infiltrates.¹⁶⁵ In additional adult-predominant clinical trials, fluconazole has been compared to posaconazole in patients with prolonged neutropenia,³⁴ to voriconazole in allogeneic stem cell transplant recipients,¹⁷¹ and to micafungin in stem cell transplant recipients.¹⁶³ The former study revealed that posaconazole was efficacious at reducing invasive aspergillosis, whereas the latter studies suggested that voriconazole and micafungin prophylaxis trended toward improved protection against invasive aspergillosis as compared to fluconazole. Collectively these data have supported adult guideline recommendations to administer antifungal prophylaxis in patients considered high-risk for IFD. However, the different adult guidelines were not consistent as to when to administer fluconazole and when to escalate to antimold prophylaxis.^{53,88}

Pediatric-specific data for antifungal prophylaxis from randomized clinical trials are not available. Based on the available adult data, pediatric guidelines support fluconazole prophylaxis during periods of neutropenia for children with AML and those receiving an allogeneic HSCT.¹⁴³ The benefits of broadening prophylaxis to include antimold coverage in a pediatric population are not yet well defined. Currently a randomized trial sponsored by the Children's Oncology Group is actively enrolling patients to compare the efficacy of caspofungin to fluconazole prophylaxis in pediatric patients with AML. The outcome of this study should inform the importance of antimold activity in a fungal prophylaxis regimen for patients at high risk for IFD.

Hospital Infection Control Practices

Children receiving chemotherapy represent a patient population at high-risk for hospital-acquired infection (HAI) because they often require prolonged hospital admissions during which they are immunosuppressed. Recently McCullers et al. documented the impact of HAIs at a single institution. Not unexpectedly, depth (<100/mm³) and duration of neutropenia as well as prolonged length of stay were identified as risk factors for a HAI. Over the 26-year study period, they documented a decrease in the rate of HAIs that correlated with the implementation of various infection control initiatives.¹⁰⁴

These data strongly support the potential impact of infection control practices in reducing HAI even in patients who are vulnerable to opportunistic infections. Important infection control practices often focus on interrupting the transmission of infectious pathogens from health care workers (HCW) to their patients. Such practices include programs to promote high compliance of hand hygiene and optimization of HCW influenza vaccination.^{18,50,145} Enacting a mandatory vaccination policy has proved to result in near complete HCW vaccine coverage at a large children's hospital.⁵⁰ Furthermore devising a hospital plan to

change the “working while sick culture” is of particular importance for HCWs attending to this patient population.¹⁵⁵ Finally, utilization of a protocol to screen visitors prior to entering the patient room can serve as a mechanism to reduce unnecessary patient exposures.

Despite the importance of infection control practices, there is likely significant variation in policies from one institution to the next, as well as variation in enforcement of policies within an institution. Enhanced efforts are needed to establish goals for reducing HAIs and to establish guidelines for standardized infection control practices specific to pediatric oncology patients in order to achieve these goals. It is also important to realize that infection control practices are important in the ambulatory setting because increasing proportions of care are being transitioned from the inpatient to the outpatient setting. Ultimately the institution of any standardized infection control practice should be accompanied by an institutional-level surveillance of HAIs to monitor the effectiveness of each intervention.

Advances in supportive care continue to lead to improvements in hematopoietic stem cell transplant (HSCT) outcomes. The 1-year transplant-related mortality (TRM) rate for children with acute leukemia and unrelated donor HSCT performed before 1995 approached 40%. More recently, rates from 2003 to 2006 fell by more than half to approximately 15%,¹³⁷ and the 3-year TRM rate continues to fall, from 27% in 2000–04 to 21% in 2005–09.¹³⁹ Furthermore over the course of the past decade, utilization of umbilical cord blood units and haploidentical donors have become standard of care. This has led to significantly more alternative donor HSCTs performed for a wide variety of non-malignant diseases, including T-cell and phagocyte primary immunodeficiencies, hemoglobinopathies, bone marrow failure syndromes, and metabolic syndromes. However, these children often have relatively intact immune systems at the time of HSCT and thus require increased pre-HSCT immunoablation to prevent graft rejection. This often leads to delays in post-HSCT immune reconstitution, which in turn is associated with significant opportunistic infections. In addition to causing significant morbidity and prolonged hospitalizations, opportunistic infections are directly responsible for 25% to 27% of transplant-related mortality following allogeneic HSCT.¹⁷⁸

Evidence indicates that certain opportunistic infections may play a role in the triggering of alloreactivity and graft-versus-host disease (GVHD). For example, animal models suggest that administration of probiotics may alter the intestinal microflora and decrease inflammation in mesenteric lymph nodes, thereby abrogating GVHD,⁷² and human studies have demonstrated that low intestinal microbial diversity at transplant is associated with poor survival, primarily due to the subsequent development of severe GVHD.²²⁸ A randomized trial of fluconazole versus placebo demonstrated less severe GVHD of the intestinal tract in the fluconazole recipients, possibly as a result of decreased intestinal antigenic stimulation.¹⁴⁷ Some data suggest that both cytomegalovirus (CMV) and human herpesvirus-6 (HHV-6) reactivations can trigger the development of GVHD.^{3,136,184} Because GVHD is another significant component of transplant-related mortality following allogeneic HSCT, further understanding of the interplay between opportunistic infections and initiation of GVHD may provide another avenue toward making HSCT a safer procedure with improved overall outcomes.

EPIDEMIOLOGY

Although opportunistic infections do occur after autologous HSCT, the much more profound and ongoing T-cell dysfunction that occurs before and after allogeneic HSCT makes opportunistic infections far more likely to occur in this population. Multiple therapy-induced alterations of host defenses contribute to this risk.¹²⁵ The three major contributors to the development of an opportunistic infection are (1) breakdown in natural barriers (e.g., indwelling central venous catheters and mucositis), (2) defects in cell-mediated immunity (e.g., lymphopenia from corticosteroids and other anti-T-cell cytotoxic agents), and (3) deficient numbers of phagocytes (e.g., as a result of myeloablative chemotherapy). Knowledge of the timing of the variety of infections that can occur after HSCT allows clinicians to develop rational approaches to antimicrobial prophylaxis, diagnostic monitoring for infections, and earlier treatment of proved infections. Classically three phases of risk for opportunistic infections occur after HSCT, as shown in Fig. 69.1.²³¹

Phase I: Preengraftment (<30 Days)

Infections in phase I of HSCT are similar to those seen with other forms of profoundly myelosuppressive chemotherapy, and include

gram-positive and gram-negative bacteremia, candidemia, invasive aspergillosis, and reactivation of herpes simplex virus contributing to oral mucositis. Administration of granulocyte-colony stimulating factor (G-CSF) during this period will shorten the time to recovery of neutrophils by several days and may decrease rates of documented infections.⁵⁵ However, less evidence exists that G-CSF improves infection-related or transplant-related mortality, and it may increase the incidence of acute GVHD.²³³ Therefore only approximately 60% of HSCT centers use G-CSF routinely.¹²¹

Phase II: Early Postengraftment (30 to 100 Days)

Some infections in phase II are caused by a combination of persistent defects in the function of the patients' phagocytes (partly from the administration of corticosteroids to treat acute GVHD) and retention of central venous catheters, which can lead to gram-positive bacteremia and candidemia. Other infections are due to the ongoing relative and functional lymphopenia and involve reactivations of CMV and other double-stranded DNA (dsDNA) viruses, *Pneumocystis jiroveci*, or certain parasitic infections.

Phase III: Late Postengraftment (>100 Days)

Infections in phase III are generally caused by ongoing immunosuppressive therapy for the treatment of chronic GVHD, which also is associated with functional asplenia. Thus patients can develop infections with encapsulated bacteria, *P. jiroveci*, and dsDNA viruses. There is also an important second peak of invasive aspergillosis during this time.

MAJOR TYPES OF OPPORTUNISTIC INFECTIONS AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION

Bacterial

Classic Gram-Positive and Gram-Negative Bacteria

Bacterial infections after HSCT most commonly divide into gram-positive organisms originating from the skin or gastrointestinal tract and gram-negative organisms translocating from the gastrointestinal tract. The period of highest risk for bacterial bloodstream infections, especially with enteric gram-negative rods, is the pre-engraftment period,³³ during which the incidence of bacteremia can range from 21% to 34% and 21% to 58% for patients undergoing autologous and allogeneic HSCT, respectively, although some studies report no difference between the two groups.^{28,30,32,34,166} In HSCT recipients, bloodstream infections before engraftment are a significant independent predictor of mortality.^{1,187} Several studies have demonstrated that either host or donor polymorphisms in genes responsible for immunity may contribute to the risk for bacterial infections.^{7,41,122,157,197,242}

Given the significant risk for developing bacteremia, it is surprising that there is little evidence that routine antibacterial prophylaxis plays a role in pediatric HSCT recipients. In adult patients undergoing HSCT, general consensus exists regarding the utility of a prophylactic quinolone with antipseudomonal activity²³¹ based on several small trials included in larger meta-analyses.^{69,98} The rates of fever and bacteremia are significantly reduced in patients receiving levofloxacin, but the impact of prophylaxis on mortality is less clear.^{26,69,98} Similar results have been reported using ciprofloxacin and vancomycin as a prophylactic regimen for autologous and allogeneic HSCT patients.^{63,212} Few of the trials stringently evaluated rates of quinolone resistance, although one recent retrospective report suggested it has not increased in the era of routine prophylaxis.¹⁶³ All of these studies were done in adult patients; therefore

FIG. 69.1 The phases of opportunistic infections after allogeneic HSCT. EBV, Epstein-Barr virus; HHV, human herpesvirus; NK, natural killer; PTLD, posttransplant lymphoproliferative disease. (From Tomblyn M, Chiller T, Einsele H, et al. Guidelines for preventing infectious complications among hematopoietic cell transplantation recipients: a global perspective. *Biol Blood Marrow Transplant*. 2009;15:1143–238.)

caution must be used in applying the specific results to pediatric HSCT recipients. The Children's Oncology Group (COG) recently completed a large randomized trial in pediatric HSCT recipients, the pending results of which may inform future practice.

Other approaches to antibacterial prophylaxis use nonsystemic treatments to potentially spare medication toxicities and the development of resistant organisms. Chlorhexidine gluconate is an antiseptic bactericidal to gram-positive and gram-negative bacteria, including multidrug resistant organisms. The mechanism of action involves bacterial membrane disruption; its onset is relatively rapid, and the effect is persistent. A 2% chlorhexidine gluconate (CHG)-impregnated cloth product has been shown to be effective at decreasing central-line associated infections and acquisition of multidrug-resistant organisms as a skin cleansing product in the critical care setting in both adults^{15,46,185,246} and children.¹⁶⁴ However, the effectiveness of CHG bathing outside of the critical care setting is controversial, with only one study showing a possible benefit⁴⁷ and another demonstrating increasing CHG-resistance.²²⁷ An ongoing randomized trial by the COG may provide insight on the effectiveness and safety of CHG bathing on bloodstream infections in children undergoing HSCT. Similarly, because many cases of bacteremia are seen in the setting of central venous catheters, the use of ethanol lock solutions may potentially decrease central venous catheter colonization without the concern of resistance from antibiotic locks. However, results from randomized trials in adults receiving chemotherapy or HSCT have been controversial, with one demonstrating the benefit of ethanol locks versus heparin²⁰⁴ and another showing no benefit.²⁶⁵ Studies of prophylactic ethanol locks in pediatric HSCT recipients are currently lacking.

When patients develop a fever early after transplant during the neutropenic period, empirical antibacterial treatment is usually started. Although a variety of different regimens exist, they are generally tailored to cover *Streptococcus* spp. and *Staphylococcus* spp., plus enteric gram-negative organisms, based on local susceptibility patterns. Recent consensus statements have favored monotherapy, with combination therapy reserved for clinically unstable patients,¹²⁶ especially as

additional reports suggest a role for anti-anaerobic antibiotics in decreasing intestinal diversity and subsequently altering immune reconstitution post-HSCT.¹⁰²

Clostridium difficile

Although hardly unique to the pediatric HSCT population, because of the widespread use of broad-spectrum antibiotics for empirical therapy of febrile neutropenia *Clostridium difficile*-associated diarrhea is not uncommon. In adults, approximately 10% to 15% of patients may develop this complication within 30 days of HSCT,^{113,257,267} although pediatric patients may behave differently, with later onset of disease.²⁴ The disease tends to be relatively mild, but relapses are very common.¹⁰⁵ Prevention of *C. difficile* may potentially be accomplished through the administration of certain strains of probiotics.¹⁵⁴ A small pilot trial suggests that this practice may be safe in the immediate post-HSCT phase, even during the period when a combination of neutropenia and compromised intestinal integrity could theoretically lead to the development of bacteremia from the ingested strain,⁸⁶ as long as the strain of probiotic is carefully considered.¹¹⁹ Treatment of *C. difficile*-associated diarrhea in the pediatric HSCT patient is similar to that of the general population, with metronidazole or oral vancomycin, although caution must be used during the conditioning phase of HSCT, when metronidazole can enhance toxicities from radiation or busulfan.⁸³ Fidaxomicin is an attractive alternative due to lower rates of relapses (15% vs. 25%)¹³⁵ and potentially improved sparing of the intestinal microbiota,¹³⁴ which in turn may decrease incidence of severe GVHD. The experience with fecal microbiota transplant after HSCT is still very limited,⁵⁴ so it is unclear at this time whether that will ultimately prove to be a safe option.

Encapsulated Organisms

Patients with chronic GVHD appear to have defects in their splenic function, and thus encapsulated bacteria, such as *Streptococcus pneumoniae*, have been noted to cause significant mortality. Prophylaxis with penicillin appears to diminish this risk,¹¹⁷ although the optimal

duration of treatment is not yet defined. In patients with chronic GVHD (cGVHD), serum immunoglobulin G (IgG) levels should be monitored, and, for patients with levels of less than 400 mg/dL, administration of intravenous gammaglobulin should be considered.²³¹ When to stop penicillin prophylaxis in relation to resolution of cGVHD is unknown because robust methods to measure splenic function, such as pitted red blood cell percentage and nonswitched memory B cells,¹²⁰ have not been tested in a post-HSCT population.

Mycobacteria

Although less common than invasive fungal infections, infections with mycobacteria must always be considered in the differential diagnosis of pulmonary nodules after HSCT. In developed countries, classic *Mycobacterium tuberculosis* infections are very rare in children undergoing HSCT, although it always should be considered in patients whose households have recently immigrated.⁷⁰ More commonly encountered are environmental atypical nontuberculous mycobacteria (NTM), which can cause infections in the lungs, skin, lymph nodes, and bloodstream. Because of the relative rarity of NTM infections, a general paucity of literature exists in the HSCT population. NTM infections have been reported to occur in as many as 9.7% of T-cell depleted and 7% of conventional allogeneic HSCTs in adults, although the mortality rate was low.²⁵⁶ Pediatric HSCT recipients have a somewhat lower rate of NTM infections (3.8%), which occur at a median of 115 days (range, 14 to 269 days) after HSCT,²³⁷ while a more recent report suggests an even lower incidence (0.2%).¹⁶⁷

The exact risk factors associated with the development of NTM infections after allogeneic HSCT are not well characterized. The protective immunity against NTM infections appears to be primarily driven by interferon- γ (IFN- γ) production by T cells, as evidenced by the high rate of NTM infections in patients with IFN- γ deficiency.⁸⁸ Thus T-cell depletion (ex vivo or with T-cell-depleting antibodies) or treatment of GVHD with immunosuppressants that block IFN- γ might be expected to be risk factors for the development of NTM infections. Similarly patients with an underlying T-cell immunodeficiency might be colonized with an NTM organism pre-HSCT that puts them at risk for developing NTM disease after HSCT. The optimal treatment of NTM infections is not clear. A wide variety of traditional antibiotics and antituberculosis agents have some activity against NTM organisms, but reports vary on the number of agents that must be used in combination and the duration of optimal therapy. In patients with human immunodeficiency virus (HIV) infection, the general recommendation is to treat most cases of NTM infections for 12 months after establishment of negative cultures.⁸² It is not clear that such a prolonged duration is required for HSCT recipients who, in the absence of chronic GVHD, tend to have improvement in, and even normalization of, their T-cell function over time.

Fungal

Although bacteria represent the most common infection after HSCT, invasive fungal infections account for a significant amount of post-transplant mortality. Several retrospective reports on the development of invasive fungal infections in pediatric HSCT recipients have been published, with a 1-year incidence as high as 12% to 20% and a 58% to 83% mortality.^{13,58,95,96,202} The most commonly identified invasive fungal organisms after HSCT are *Candida* and *Aspergillus* spp. Patients who are considered to be at the highest risk for developing an invasive fungal infection after HSCT are those who undergo transplant from either an unrelated donor (including umbilical cord blood) or a partially matched related donor or for treatment of a malignancy, bone marrow failure syndrome, or congenital immunodeficiency, and those receiving high-dose corticosteroids.^{27,58,95,116,147,160,231}

Currently the use of antifungal prophylaxis is nearly universal in HSCT patients. Empirical therapy directed against resistant *Candida* or molds generally commences after approximately 72 hours of prolonged fevers despite administration of broad-spectrum antibacterials. One surprising feature to note from the original prophylactic fluconazole studies is that, even in the placebo arm, more than 80% of HSCT patients did not develop an invasive fungal infection, although these studies did include lower-risk autologous HSCT recipients.^{77,218} This suggests that other explanations must exist for the development of

invasive fungal infection after HSCT. Researchers are now finding that either host or donor polymorphisms in genes responsible for immunity appear to play a significant role in invasive fungal infection risk.^{17,53,80,111,159,211,266} Most of these proposed genetic risk factors still require validation in a prospective multicenter cohort, but the future possibility of having different prophylactic strategies based on an a priori risk for developing an invasive fungal infection is promising.

Candida

Invasive candidiasis tends to occur during the neutropenic period immediately after HSCT, although later cases can occur in the setting of GVHD and prolonged immunosuppression, especially when central venous catheters are still in place. Typically invasive candidiasis originates from endogenous *Candida* spp. colonizing patients' gastrointestinal tracts.⁴⁹ Pediatric patients appear to have relatively more invasive infections caused by *C. parapsilosis* and fewer infections caused by *C. glabrata*, in contrast to adults.¹⁴⁰ Two placebo-controlled trials from the early 1990s, performed in patients older than 12 years of age undergoing autologous or allogeneic HSCT, demonstrated that prophylactic administration of fluconazole significantly decreased invasive fungal infections.^{77,217} Long-term follow-up of allogeneic HSCT recipients given fluconazole prophylaxis supports a survival benefit (mortality 20% in the fluconazole arm vs. 35% in the placebo arm; $P = .004$), postulated to be at least partly due to less severe GVHD in the fluconazole recipients from decreased antigenic stimulation,¹⁴⁷ which may be mediated by T_H17 polarization in response to components of the fungal cell wall.²³⁸ The classic duration of fluconazole prophylaxis administration is during the high-risk period until 75 days after HSCT.^{145,147} Because fluconazole does not cover *C. krusei* and has variable activity against *C. glabrata*, alternative agents should be considered for patients known to be colonized with these species. Reasonable options include extended-spectrum triazoles, echinocandins, and lipid-formulations of amphotericin B (LFAB), all of which also have some coverage against *Aspergillus* spp.

When patients develop invasive candidiasis after HSCT, the most common site of infection is the bloodstream. In addition to initiation of appropriate antifungal agents, the standard practice is to discontinue all central venous catheters in patients with candidemia.¹⁸⁹ Less common, but more perplexing, disseminated *Candida* infections of the liver, spleen, or lungs can often be blood culture-negative and may require tissue biopsy to establish a diagnosis. Serum β -glucan levels may be useful for identifying cases of possible invasive candidiasis once the assay has been optimized for use in children.²²⁰ Furthermore in patients with disseminated candidiasis, a formal ophthalmologic evaluation is recommended to rule out *Candida* endophthalmitis, which may require intravitreal injection of antifungal agents to preserve vision.¹⁹⁵ For treatment of invasive candidiasis, especially those cases that develop on fluconazole prophylaxis, the echinocandins are a class of antifungal agents that target β -(1,3)-D-glucan synthase and interrupt biosynthesis of the glucan polymers that make up fungal cell walls. Because mammalian cells do not possess cell walls, echinocandin administration to human patients has generally resulted in limited toxicity. Echinocandins possess fungicidal activity against most *Candida* spp.; however, *C. parapsilosis* may be less sensitive.⁵ In some settings, the echinocandins may be superior to fluconazole¹⁹¹ or amphotericin B¹⁶⁵ for treatment of invasive candidiasis.

Aspergillus

In adult HSCT recipients, *Aspergillus* spp. time of infection has a bimodal distribution, with a first peak at a median of 16 days and the second at a median of 96 days after allogeneic HSCT.^{239,241} This second peak may be less pronounced in children.³² Invasive aspergillosis can be one of the most devastating infections to occur after allogeneic HSCT. In a multivariate analysis of risk factors for mortality among a modern cohort of pediatric patients with invasive aspergillosis, the major risk factor for death was the development of invasive aspergillosis after an allogeneic HSCT.²⁷ Although treatment options for invasive aspergillosis have increased in recent years, significant attention also has been paid to preventing invasive aspergillosis infections. Although fluconazole prophylaxis has been shown to reduce the risk for invasive fungal infection relative to placebo, fluconazole lacks activity against *Aspergillus* spp.

Given this lack of antimold activity, several trials have compared fluconazole to mold-active agents in hopes of decreasing rates of invasive aspergillosis. The first of these trials compared fluconazole to low-dose conventional deoxycholate amphotericin B (D-AMB).²⁶³ However, D-AMB did not show improvement over fluconazole and resulted in a higher adverse event rate. Several trials, including one in children,¹⁹⁹ have evaluated the LFAB (often given only three times per week) for antifungal prophylaxis in HSCT and acute leukemia patients.^{110,153,181} However, like D-AMB, LFAB has not been shown superior to fluconazole in overall success and typically demonstrates increased side effects.

Extended-spectrum triazoles such as itraconazole, voriconazole, and posaconazole do possess anti-*Aspergillus* activity⁵; however, clear limitations exist to each as a potential prophylactic agent. Several trials of itraconazole versus fluconazole have been performed, and a meta-analysis showed significantly less invasive fungal infections,²⁴⁴ but because of its common gastrointestinal side effects, greater drug interactions, and poor tolerability,¹⁴⁵ itraconazole prophylaxis has generally been abandoned in children. The results of a multicenter, double-blinded trial showed that voriconazole was not superior to fluconazole in the prevention of invasive fungal infection, although the safety profile was similar.²⁶⁰ Given voriconazole's broader spectrum of activity, this result was surprising but may have been due to an incomplete understanding of the complex pharmacokinetics of voriconazole. In adults and children over the age of 12 years, voriconazole has nonlinear pharmacokinetics with relatively well-established dosing regimens. Even in adults, however, recent studies have questioned standard dosing regimens and have proposed dosing based on serum drug levels,^{177,221,232} with an optimal goal serum voriconazole level of 1 to 5.5 µg/L. Part of this variability may be due to allelic polymorphisms of the gene encoding for cytochrome (CYP)2C19, which can result in an increase or decrease in voriconazole metabolism,¹⁷⁷ and basing dosing on CYP2C19 genotype can improve the number of patients in the target range.²²⁹ In children, the situation is further complicated by linear voriconazole kinetics, so that younger children may need significantly higher dosages of voriconazole.^{67,107,169} Voriconazole also has significant drug interactions with commonly used agents in a pediatric HSCT population. Voriconazole is a substrate of CYP2C9 (major), 2C19 (major), and 3A4 (minor) and an inhibitor of 2C9 (moderate), 2C19 (weak), and 3A4 (moderate).⁵² Proton pump inhibitors increase voriconazole levels, while voriconazole increases serum levels and toxicity of corticosteroids, imatinib, and many other medications.⁵² The approved voriconazole label reports that concomitant use of voriconazole can cause a 1.7- to 3-fold increase in cyclosporine or tacrolimus levels and recommends that the dosing of cyclosporine be decreased by 50% and the dosing of tacrolimus be decreased by 66% of the normal dose. Furthermore the use of voriconazole with sirolimus is officially contraindicated, and when its use has been reported, investigators have recommended dropping the levels of sirolimus by 90% of original dosing at the time of initiation of voriconazole.¹⁵⁰ Finally extended use of voriconazole has been linked to fluoride-induced periostitis⁹ and severe phototoxicity, including development of non-melanoma skin cancers.²¹⁶

Posaconazole is a triazole with broad coverage of most fungi, including mucormycosis (previously called zygomycosis).⁵ In a trial of adult patients with neutropenia, posaconazole prophylaxis was superior to fluconazole or itraconazole but was also associated with an increased risk for serious adverse events.⁵¹ In a trial of teenagers and adults receiving treatment for acute or chronic GVHD, posaconazole was superior to fluconazole at preventing breakthrough and death from invasive fungal infection, with similar rates of toxicity.²³⁶ Unfortunately this did not translate to improved overall survival. Posaconazole also shares many of the same enzymatic pathways—and therefore drug interactions—as voriconazole, albeit without the bone and skin toxicities.

Isavuconazole is the newest triazole and, like posaconazole, has broad coverage of invasive fungi. A phase 3 trial for treatment of invasive molds demonstrated noninferiority to voriconazole and lower rates of toxicities, including hepatotoxicity, visual disorders, and skin disorders.¹³⁸ It has also been used successfully as prophylaxis in neutropenic adult patients with acute myeloid leukemia (AML) in a phase II trial.⁵⁰ It has excellent bioavailability regardless of food intake and is also available intravenously, with early suggestions that therapeutic drug level

monitoring may not be required. However, it still has moderate inhibition of CYP3A4, and modifications of GVHD prophylaxis agents will be required. Finally pediatric experience and dosing information is currently extremely limited. Because of the CYP interactions, azole prophylaxis when used is generally started after the conditioning regimen is complete. For patients who enter the HSCT period being treated for a preexisting invasive fungal infection, discontinuation of azoles 72 hours before the start of conditioning chemotherapy is often done to allow the CYP enzymes to return to baseline function, although some data suggest that fluconazole coadministration may actually help with cyclophosphamide metabolism and decrease toxicity.²⁴¹

Echinocandins possess fungistatic activity against *Aspergillus* spp.⁵ In a prophylactic antifungal trial, micafungin demonstrated reduced need for empirical antifungal therapy and an improved safety profile in contrast to fluconazole.²⁴⁰ However, the number of pediatric subjects enrolled was small ($n = 84$), and a reduction in the incidence of proved or probable invasive fungal infection was not demonstrated. The lack of impact on invasive fungal infection may have been because the incidence of breakthrough invasive fungal infections in both groups was very low, likely as a result of the inclusion of low-risk patients (46% autologous HSCT recipients) and very few patients undergoing umbilical cord blood transplant ($n = 30$). Caspofungin has been shown to be at least equivalent to itraconazole in the setting of antifungal prophylaxis,¹⁵² with few caspofungin-related adverse events.⁴⁵ The COG is conducting a large multicenter prospective trial in the pediatric HSCT population in North America. The major disadvantages to widespread echinocandin use are cost and the lack of an oral formulation.

If prophylaxis fails, the typical locations where invasive aspergillosis develops after an allogeneic HSCT are the lungs and sinuses, with not uncommon seeding of the brain. It should be noted that children do not always display the classic radiographic findings seen in adults with invasive aspergillosis, such as the air crescent or halo signs,²⁷ and a high index of suspicion must be maintained. Much attention has been focused on developing noninvasive tests for diagnosing invasive aspergillosis. Galactomannan is a polysaccharide cell-wall component released by *Aspergillus* during growth. The Platelia EIA *Aspergillus* galactomannan assay was approved by the U.S. Food and Drug Administration in 2003 for use in adult patients and, in 2006, in children.¹⁸³ Early large-scale clinical testing included few children, but available data suggest that detection values for adult patients can be extrapolated to children.^{89,225} Serum β-D-glucan (found in all fungi except *Cryptococcus* spp. and mucormycosis) can be detected using an approved diagnostic serum assay and has been found to have high specificity and high positive predictive values for the detection of invasive fungal infection in adults.¹⁷³ However, data on the performance of this assay in children are limited, especially in the post-HSCT setting.²²⁰ Ultimately obtaining cultures through bronchial alveolar washings or biopsy is the best way to be certain of what organism is being treated. Speciation of the *Aspergillus* is also important if polyene therapy is planned because of the intrinsic resistance of *Aspergillus terreus* to amphotericin B.⁵⁶

Based on a pivotal trial performed in teenagers and adults, voriconazole has become the standard therapy for patients with invasive aspergillosis,⁹¹ although the recent success of the apparently less toxic and erratic isavuconazole may alter this approach.¹³⁸ Because of the high mortality rate of invasive aspergillosis in post-HSCT patients, there has been great enthusiasm for potentially synergistic combination therapies, such as with a triazole and an echinocandin,¹⁴³ and a prospective trial suggested that this combination was safe and more effective than a triazole alone in some specific patients with proven infections.¹⁴⁶ If amenable to a surgical approach, strong consideration should be made for resection of cases of invasive aspergillosis, which has been shown to improve mortality if disease is precariously located near a major vessel.²⁷ During the neutropenic period in patients who develop invasive aspergillosis, transfusions of irradiated random donor granulocytes have been proposed as a method to improve outcomes, although conclusive proof that this laborious procedure is beneficial is lacking, although a recent trial suggested some benefit if the infused cell doses were high.¹⁸⁸ Finally exciting work has demonstrated the importance of adaptive immunity to fighting invasive aspergillosis.⁹⁰ Based on this, work has been done on creating *Aspergillus*-specific T cells for use in adoptive

immunotherapy. It has been demonstrated that a cohort of patients who developed invasive aspergillosis after haploidentical HSCT and who received *Aspergillus*-specific T cells had significantly better resolution of the infection than a similar cohort not given the specific T cells.¹⁸²

Rare Fungi

Less frequently, infections occur with the agents of mucormycosis (*Mucor*, *Rhizopus*, and *Absidia* spp.), *Trichosporon* spp., *Fusarium* spp., and other saprophytic fungi.^{144,194,255} For these rare fungi, the key is to obtain culture identification, by biopsy if necessary, so that the optimal antifungal agent may be initiated. Posaconazole is a triazole with broad coverage of most fungi, including mucormycoses⁵ and thus may be the optimal treatment for many of these organisms despite all of the caveats mentioned earlier regarding this agent. The newer agent isavuconazole also has activity against mucormycosis.¹³⁸ Recent work has demonstrated that Mucorales-specific T cells are generated after an infection with these organisms and thus might be useful as a diagnostic marker,¹⁸⁶ but also suggested that generation of similar cells for treatment of Mucorales infections may one day be possible.

Pneumocystis jiroveci

Previously referred to as *Pneumocystis carinii*, *Pneumocystis jiroveci* refers to the distinct species that infects humans. The abbreviation PCP (or now PJP) is often used to refer to pneumocystic pneumonia. PJP reactivations or infections are generally thought to be preventable after HSCT with administration of prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX). However, in the setting of alternative prophylaxis agents or TMP-SMX noncompliance, episodes of PJP may rarely occur beginning about 2 months after HSCT and continuing through recovery of T-cell functional immunity and is associated with increased mortality.²⁵⁹

TMP acts by interference with the bacterial dihydrofolate reductase, inhibiting synthesis of tetrahydrofolic acid and thus nucleic acid synthesis. Because of concerns about bone marrow toxicity, TMP-SMX is often held for several weeks after HSCT until evidence of neutrophil recovery, although this practice has been challenged.⁶⁶ The necessary amount of TMP-SMX required to prevent PJP has not been well studied, and a variety of dosing regimens exist, with administration 2 or 3 days per week being the most common.²³¹ Generally TMP-SMX is continued for at least 6 months after an allogeneic HSCT, although this should be lengthened for patients receiving ongoing immunosuppressive therapy.²³⁴ In addition to possible bone marrow suppression, many patients have allergic or other reactions to TMP-SMX that induce clinicians to prematurely discontinue its use. However, the optimal second-line prophylactic agent is not well defined, and all options may be potentially less effective than TMP-SMX. Options that have been used include oral dapsone, intravenous or inhaled pentamidine, and oral atovaquone. Dapsone is inexpensive but has a high incidence of adverse events, especially in patients with glucose-6-phosphate deficiency.²⁰⁵ Intravenous pentamidine given every 4 weeks also has been used, although inadequate protection has been noted in children under 2 years of age and those undergoing HSCT,¹¹² who may need more frequent dosing.¹²⁹ Aerosolized pentamidine is generally well tolerated, other than occasional bronchospasm, but its effectiveness has been questioned.²⁴⁵ Atovaquone is generally well tolerated, but absorption can be limited in patients not eating diets containing fatty foods. In vitro, the echinocandin class of antifungal agents appear to have some activity against the cyst form of *P. jiroveci*. To date, no studies have evaluated the use of echinocandins as a solitary prophylaxis agent; however, a few case reports have described its potential utility in combination with TMP-SMX for the treatment of PJP.^{2,12}

PJP must be suspected in HSCT patients presenting with hypoxemia (often disproportionately more severe than the degree of hypercapnia), dyspnea, cough, fever, and bilateral infiltrates,^{215,234} especially if non-compliance is suspected or alternative prophylaxis agents have been used. Although it is highly sensitive in patients with HIV infection, measuring the serum lactate dehydrogenase level is less useful in other immunocompromised patients because of low levels of sensitivity and specificity.²⁵⁰ Serum β -D-glucan levels could potentially be very useful for identifying cases of PJP once the assay has been optimized for use in children.²²⁰ Until then, the definitive diagnosis of PJP still requires

identification of the organism on special stains or polymerase chain reaction (PCR) of induced sputum or bronchoalveolar lavage fluid.²¹⁵ Once PJP is identified, the treatment of choice is high-dose TMP-SMX (15 to 20 mg TMP/kg per day divided every 6 hours).²¹⁷ This high-dose TMP-SMX may be difficult to administer to a patient recovering from HSCT with marginal bone marrow reserves. Therefore some physicians have used folinic acid “rescue,” analogous to what is used after methotrexate administration, with the hypothesis that bacteria are unable to take up the folinic acid from the environment and thus only the host bone marrow cells are helped. Although no data exist in children undergoing HSCT, caution should be used with this approach because it has been associated with increased treatment failures in patients with HIV infection.²⁰³ Although counterintuitive in a patient with poor T-cell function, TMP-SMX has been combined with a short course of corticosteroids, which appears to be beneficial in preventing temporary worsening of hypoxemia resulting from inflammation caused by dying organisms. The recommended dose is prednisone 1 mg/kg per dose twice daily (maximum 40 mg twice daily) (or the equivalent dose of methylprednisolone) tapered in half after 5 days and then again in another 5 days, then discontinued after 21 days.¹⁰⁶ It should be noted that these data derive solely from the HIV literature in adults, and it is unclear whether this approach is safe or beneficial in pediatric HSCT patients.

Viral

Viral infections after pediatric HSCT can be divided into two broad categories: DNA viruses that occur as a result of reactivation of a previous infection (and occasionally as a de novo infection) and community-acquired respiratory as well as enteric viruses. Other than donor and recipient serostatus, the major risk factor for reactivation of a dsDNA viral infection after HSCT is the use of T-cell depletion, either ex vivo or in vivo with serotherapy.^{48,168,176} Recently a few polymorphisms in host immune response genes also have been shown to possibly contribute to the development of dsDNA viral infections after HSCT.^{21,22,101}

Herpes Family Viruses

Herpes simplex virus. Herpes simplex virus-1 (HSV-1) and HSV-2 infections after HSCT usually occur as a result of reactivations from a previously acquired latent virus. Thus, pretransplant serologies are very useful in identifying at-risk patients. Because acquisition of HSV occurs as patients age, many pediatric HSCT recipients will be seronegative. In the era before routine prophylaxis of seropositive patients, reactivation rates were approximately 70% to 80% and significantly contributed to post-HSCT mucositis.²⁰⁶ Dissemination of HSV to the lungs, liver, or brain is also possible. Routine acyclovir prophylaxis is usually given during the period of mucositis, and, with this, HSV reactivations are relatively rare⁷⁶ and screening of serum by PCR is likely of little benefit.¹⁷⁹ However, severely immunocompromised individuals can continue to develop reactivations for many months after HSCT, and thus some centers will continue prophylaxis for up to 6 months,¹³³ a typical period for development of T-cell reconstitution in the absence of GVHD. This is not needed for patients who receive ganciclovir for CMV prophylaxis because ganciclovir also has activity against HSV.⁷⁸ In addition, some strains of HSV have become acyclovir-resistant, and thus patients with mucositis more severe than anticipated should have a lesion swabbed for HSV culture and resistant strains treated with either foscarnet or cidofovir.^{68,231}

Routine acyclovir prophylaxis does not appear to have a role in HSV-seronegative patients, although consideration of varicella zoster virus (VZV) serostatus also must be taken into account. Furthermore patients with B-cell immunodeficiencies may be unable to mount an antibody response before HSV infection and should be considered for prophylaxis, especially if close contacts such as the parents or siblings have a history of HSV infections.

Cytomegalovirus. Historically one of the most severe complications of allogeneic HSCT was CMV infection. In the modern era, the use of PCR-based detection strategies has significantly reduced the incidence of CMV disease. More than 50% of healthy adults in the United States are CMV seropositive, and the incidence increases with age, with 36% of children 6 to 11 years of age already exposed.²²⁴ With the use of

CMV-negative blood products, the rate of de novo infection in CMV-seronegative donor and recipient (D⁻R⁻) pairs after HSCT is as low as 2%.¹⁷¹ Thus most infections occur as a result of reactivations, likely of host CMV, because infections are much less common in donor-positive, recipient-negative (D⁺R⁻) transplants than in those in which the recipient is positive (D⁺R⁺ or D⁻R⁺).¹⁷¹ Other factors can alter the risk for reactivation in a CMV-seropositive HSCT recipient. Data are conflicting on whether CMV-seropositive donors should be chosen for CMV-seropositive recipients in regard to decreasing mortality, although it does appear to result in lower rates of CMV reactivation and disease.^{207,235} After autologous HSCT, CMV reactivations are not uncommon, but CMV disease is rare²⁶¹ except in the setting of CD34 selection. T-cell depletion of donor cells in the allogeneic HSCT setting is a major risk factor for reactivation, which may occur even before neutrophil engraftment.^{92,239} GVHD and its treatment with corticosteroids, and poor T-cell reconstitution even in the absence of GVHD, are major risk factors for CMV reactivation.²⁰ Of interest, even in the absence of serotherapy, the choice of GVHD prophylaxis regimen may alter the risk for CMV reactivation. Sirolimus, an inhibitor of mammalian (or mechanistic) target of rapamycin (mTOR), appears to provide a protective effect against CMV when used in combination with tacrolimus and in place of other agents.¹⁴⁹ It remains to be determined if this effect is due to direct inhibition of CMV viral replication from sirolimus or enhanced reconstitution of anti-CMV immunity.¹⁴⁹ Overall as many as 65% of seropositive allogeneic HSCT recipients will develop CMV reactivation if not given specific prophylaxis.⁶⁰

Several agents have been used for CMV prophylaxis in at-risk patients (D⁻R⁻ patients are typically excluded). Because acyclovir has some in vitro activity against CMV, high-dose acyclovir (500 mg/m² per dose three times daily) has been shown to prevent CMV.^{158,162} Because of its improved absorption, valacyclovir may be superior to high-dose acyclovir for the long-term prevention of CMV reactivation.¹³² Ganciclovir is the most commonly used CMV prophylactic agent.²³¹ As a result of its marrow-suppressive qualities, it is typically started after neutrophil engraftment,^{18,262} although some have suggested a role for a therapeutic window during the pre-HSCT conditioning.¹⁶² In addition, ganciclovir use may partially inhibit recovery of both normal and CMV-specific T-cell function.¹⁰ Other agents, including brincidofovir¹⁵¹ and letermovir,⁴⁰ have had promising results as CMV prophylaxis in phase II studies; however, randomized phase III results are not yet available. In patients at high risk for early CMV reactivation before neutrophil recovery, foscarnet has been used because of its lack of significant marrow suppression, although it does have significant renal toxicity.⁸ If prophylaxis is to be used, it is typically continued for 100 days after HSCT,²³¹ but longer courses may be indicated for patients with significantly impaired immune systems. All of these prophylactic strategies are generally used in combination with screening for reactivation by serum PCR.²³¹ An argument against CMV prophylaxis, at least in certain patient populations, is that CMV reactivation has been shown to be protective against relapse in patients with AML⁶⁴ undergoing myeloablative conditioning,¹⁴¹ possibly from stimulating a graft-versus-leukemia effect. However, due to the increased risk of TRM associated with the CMV itself, this benefit does not produce any difference in overall survival.⁸¹ Because all of the anti-CMV agents have some degree of toxicity, the alternative strategy to prophylaxis is preemptive treatment based on detection of CMV viremia. A randomized trial comparing prophylaxis versus preemptive management of CMV showed similar outcomes.¹⁸ Patients are screened at least once weekly for CMV DNA and specific antiviral therapy begun once a threshold amount of virus has been detected. Ganciclovir is the most common first-line agent used,²³¹ although foscarnet can be considered in patients with poor marrow reserve.¹⁹³ Even in patients with good marrow function, ganciclovir can cause neutropenia, and its use requires monitoring of neutrophil counts and often support with G-CSF.²³¹ Typically ganciclovir is given twice daily for a minimum of 2 weeks, or longer for patients whose viremia is still detectable after 2 weeks.¹⁸ Daily maintenance ganciclovir therapy also has been used in patients at high risk for a second reactivation because of poor immune recovery. The duration of maintenance therapy can vary from 4 weeks after the first negative PCR result or up to day 100. Oral valganciclovir has become more widely used for preemptive therapy, either as a first-line

agent or to replace intravenous ganciclovir at the time of switching to maintenance therapy.⁶¹ Early in the treatment course, CMV viral loads may rise, but in antiviral-naïve patients this is typically not a sign of resistance. However, continuing increases in viral loads after 2 weeks of therapy or signs of CMV disease should raise suspicion for a resistant strain of CMV. Mutations in the CMV UL97 phosphotransferase gene typically cause resistance only to ganciclovir, so foscarnet and cidofovir remain alternative agents.^{35,57} Mutations in the UL54 viral DNA polymerase will cause resistance to ganciclovir, and cidofovir, and, occasionally, foscarnet.⁵⁷ For the patient who appears to be failing or intolerant of all three drugs, leflunomide is a third-line alternative.⁵⁹ Leflunomide is an immunomodulatory agent that inhibits pyrimidine synthesis and results in both antiproliferative and antiinflammatory effects. The active metabolite appears to inhibit replication of both CMV and human polyomavirus type I, commonly referred to as BK virus.

The role of CMV-specific antibodies, either in conventional gammaglobulin products or high-titer products, is of debatable efficacy. On the other hand, efforts to produce donor-derived CMV-specific T cells have shown great promise in treating CMV disease.⁶² Given the low rates of GVHD associated with these cells, they may be an upcoming preventive strategy.¹⁸² Furthermore the techniques that enable generation of CMV-specific T cells also can be used to generate T cells active against Epstein-Barr virus (EBV) and adenoviruses,^{73,87} as well as potentially HHV-6, BK virus, and others. These multivirus-specific cells represent an exciting avenue of adoptive immunotherapy in severely immunocompromised post-HSCT patients, although they are not yet available outside of single-center research protocols.

Epstein-barr virus. EBV infection after HSCT usually results from the reactivation of latent EBV in either residual host B cells or passively transferred donor B cells. As with other herpes family viruses, pre-HSCT serologies can help identify at-risk patients; however, because approximately 95% of adults are seropositive,¹⁴ virtually all patients undergoing adult unrelated-donor HSCT are potentially susceptible. Unlike other herpes family viruses, no clearly effective antiviral agent exists against EBV and thus no post-HSCT prophylaxis strategy exists. Fortunately the rate of EBV reactivation in patients receiving T-replete grafts is quite low. Conversely patients who receive ex vivo T-cell-depleted stem cells, anti-T-cell serotherapy, and umbilical cord blood grafts have an elevated risk.⁷⁵ EBV reactivation can lead to the development of post-transplant lymphoproliferative disease (PTLD), signs and symptoms of which can include fever, lymphadenopathy, fulminate sepsis, or mass lesions in lymph nodes, spleen, or central nervous system. Several histologic subtypes exist, and all generally occur within the first 3 to 6 months of the posttransplant period. The first step to be undertaken once an EBV infection is suspected is to reduce immunosuppression when possible.²²⁶ If that fails, because EBV proliferates primarily within B cells, administration of rituximab often is successful at eliminating the infection.²⁵³ Copy numbers of EBV in the blood can be easily monitored after HSCT by PCR (although rare cases of PTLD without EBV viremia have been noted), and routine monitoring of high-risk patients is recommended.²³¹ Less clear, however, is exactly what threshold level should be used for initiation of preemptive therapy because some patients will have transient self-limited EBV viremia after HSCT.²⁵³ Nevertheless evidence suggests that preemptive rituximab for treatment of EBV viremia is more effective than initiation once PTLD is established,²²⁶ and mortality of PTLD in HSCT recipients is low.⁷¹ Some groups have established methods for enriching for EBV-cytotoxic T lymphocytes, which can both prevent and treat EBV PTLD in high-risk patients with little risk for causing GVHD.¹⁵⁵ For centers without access to specific donor T cells, the fact that most donors are EBV seropositive allows the use of unmanipulated donor lymphocyte infusion, which is often effective, albeit with a high risk for inducing GVHD.^{93,172}

Varicella zoster virus. With the advent of routine vaccination against VZV at 1 year of age, the majority of immunocompetent patients entering HSCT are seropositive for VZV. In the absence of prophylaxis, reactivations occur in approximately 30% of patients after HSCT¹⁹ regardless of whether myeloablative or reduced intensity conditioning is used.¹⁶ A double-blinded trial of acyclovir prophylaxis given for 1 year after HSCT demonstrated a significant reduction in VZV reactivations, although this duration of treatment was inadequate in patients who

continued on immunosuppressive therapy for treatment of chronic GVHD.¹⁹ An unresolved question is whether pediatric HSCT recipients who are VZV seropositive before HSCT as a result of prior live-attenuated vaccination, rather than exposure to wild-type VZV, are at a high enough risk for reactivation to warrant long-term prophylaxis. Several case reports suggest that the live-attenuated strain is capable of causing zoster and even disseminated disease in immunocompromised children.^{38,128} Therefore, until new data are available, the recommendation for acyclovir prophylaxis should be applied to all VZV-seropositive patients.

For post-HSCT patients who are exposed to an individual with active wild-type VZV infection (including shingles) and are not receiving prophylactic acyclovir or intravenous immunoglobulin (IVIG), passive immunization with varicella zoster immunoglobulin should be initiated within 96 hours of exposure.²³¹ There does not appear to be a significant rate of transmission of live-attenuated vaccine strain VZV to immunocompromised individuals, and thus household contacts of HSCT recipients are allowed to receive the vaccine, although optimally it should be given before the HSCT when possible.²³¹

According to the 2011 Centers for Disease Control and Prevention (CDC) recommendations, patients who underwent HSCT may be vaccinated with the live-attenuated strains of VZV on a case-by-case basis after a minimum of 24 months post-HSCT. This may place patients at risk for developing a potentially serious infection during the gap period. However, two reports have since demonstrated the safety and seroconversion rates of the live-attenuated VZV vaccine when given to this patient population after first demonstrating adequate T-cell immune reconstitution.^{44,118}

Human herpesvirus-6. HHV-6 is a ubiquitous pathogen that has infected the majority of people by the age of 2 years and has been reported to reactivate in approximately 50% of HSCT recipients according to PCR-based monitoring.²⁶⁸ The majority of these episodes of viremia appear to be self-limited and asymptomatic, significantly limiting recommendations regarding preemptive therapy. However, a variety of reports have linked HHV-6 reactivations to post-HSCT fevers, rashes, hepatitis, pneumonia, and delayed engraftment,²³¹ as well as to increased TRM and poorer overall survival,³ although not all reports agree that HHV-6 is a major issue: thus universal PCR screening is controversial.²⁴⁹ HHV-6 also appears to be a rare cause of post-HSCT encephalitis, typically manifested as memory loss, seizures, hyponatremia, cerebrospinal fluid pleocytosis, and magnetic resonance imaging (MRI) abnormalities in the mesial temporal lobe.^{79,209} Patients manifesting these symptoms should have their cerebrospinal fluid examined for HHV-6 by PCR. HHV-6 replication has also been implicated in the initiation of GVHD.^{3,184} When HHV-6-associated disease is diagnosed, ganciclovir is typically the first-line agent, although both foscarnet and cidofovir also have activity against HHV-6.²⁶⁹ If the HHV-6 viremia does not appear to be resolving with antiviral treatment, the possibility of chromosomally integrated virus must be considered.¹⁰³ This can be determined by paired serum and whole blood PCRs demonstrating that the copy numbers in the whole blood sample are significantly higher and the serum copy numbers are generally very low.

Other Double-Stranded DNA Viruses

Adenovirus. A large number of serotypes of adenovirus have been implicated in causing human disease, and, by the age of 5 years, most individuals have been exposed to at least one serotype, thereby allowing latent virus to enter the system. Thereafter reactivation during a period of intense immunosuppression results in the majority of cases of adenoviral viremia after HSCT.²⁵ The major risk factor for adenoviral reactivation is the degree of immunosuppression experienced by the patient, especially among recipients of T-cell-depleted grafts or grafts from unrelated donors and those being treated for GVHD.^{37,168} Of interest, for reasons that are not entirely clear, younger age also appears to be a risk factor.²⁵

With the advent of PCR-based testing of blood and other body fluids, it has been demonstrated that adenoviral reactivations occur in approximately 27% to 32% of pediatric HSCT recipients.^{131,168} Because of this high incidence, many centers perform routine screening of blood by PCR for early detection of adenoviral reactivations in high-risk

patients.¹³¹ When adenovirus viremia progresses to invasive disease, manifestations include pneumonia, hepatitis, enteritis, cystitis, and nephritis.²⁵ Adenoviral disease after HSCT has been associated with mortality rates as high as 78%.¹⁶⁸ The only currently available agent for treatment of adenoviral viremia or disease is intravenous cidofovir, typically given on a schedule of three times per week.⁹⁴ However, intravenous cidofovir has potentially significant toxicities to both the kidneys and bone marrow. This makes its use as a preemptive agent problematic, especially when some patients appear to spontaneously clear the viremia without treatment.^{168,254} An oral liposomal formulation of cidofovir (brincidofovir) may potentially be less toxic than the intravenous formulation and may serve as a preemptive agent if FDA approved.⁶⁵ Furthermore, because the major risk factor for the development of adenoviral infection is profound immunosuppression, rapid tapering or withdrawal of immunosuppression, when possible, may potentially play a role in the treatment.³⁷ For patients who develop adenoviral infection after T-cell-depleted HSCT, researchers are also working on developing adenovirus-specific T cells for adoptive immunotherapy, either alone or in combination with specificity for other viruses.^{123,174}

Human polyomavirus type 1. Human polyomavirus type 1, typically referred to as BK virus, is a common asymptomatic infection in adults, 90% of whom are seropositive.¹¹⁵ Like other dsDNA viruses, it can reactivate during periods of intense immunosuppression, and between 50% and 80% of HSCT recipients will be found to shed BKV in their urine in the first several months after HSCT.^{4,191} Much of the time, this viremia is asymptomatic, but BK virus reactivation can be associated with the development of hemorrhagic cystitis (HC) in approximately 5% to 15% of HSCT recipients, typically 3 to 6 weeks after HSCT.¹¹ The patients at highest risk for developing BK virus-associated HC appear to be those who received cyclophosphamide-based conditioning regimens and T-cell-depleted grafts.⁴² Furthermore BK virus can be found in the blood of some patients after HSCT, and high levels have been associated with the development of BK virus-associated nephropathy,⁸⁴ which can be definitively diagnosed only by renal biopsy. Of interest, fluoroquinolone antibiotics inhibit BK viral replication in vitro, and some data suggest that their use as antibacterial prophylaxis after HSCT also may decrease rates of BK virus-associated HC.¹²⁷ Decreasing immunosuppression, whenever possible, is the first step toward treating BK virus disease. If the BK virus disease persists, cidofovir is the most commonly used antiviral agent, although leflunomide also appears to have some efficacy¹⁹⁰ and may potentially be better tolerated than cidofovir in patients with significant renal dysfunction. If approved, brincidofovir may be an attractive option for patients with severe BK virus infections.¹⁷⁵ Finally, T cells with BK virus specificity, among others, are also being generated for eventual clinical usage.⁷⁴

Respiratory Viruses

In pediatric HSCT recipients, respiratory viral infections as a whole play a significant role in TRM,⁹⁷ especially in patients with low lymphocyte counts and/or high doses of corticosteroids.²⁶⁴ They have also been reported to be associated with later development of alloreactive lung injury.²⁴⁷ As such, it has been advocated that patients should undergo, at minimum, testing for respiratory viruses pre-HSCT and delay in HSCT whenever possible²⁹ and possibly even pre-HSCT detailed pulmonary screening with high-resolution CT scan and bronchoalveolar lavage (BAL).²⁴⁸

Influenza. During seasonal outbreaks (typically October to March in the northern hemisphere), HSCT recipients are at risk for developing influenza infections from close contacts. Although upper respiratory tract symptoms are common, systemic symptoms such as fever or myalgias may be absent.¹⁸⁰ Thus a high index of suspicion must be maintained during the peak season, because 20% to 50% of influenza infections can rapidly progress to lower respiratory tract disease with hypoxemia and a risk for mechanical ventilation and death.⁴³ Bronchoalveolar lavage (BAL) may be needed in patients with evidence of lower respiratory tract symptoms because highly immunosuppressed patients are at risk for harboring multiple pathogens. Early preemptive treatment with neuraminidase inhibitors (the choice depending on that year's circulating strain) appears to be relatively efficacious at preventing

progress to lower respiratory tract disease.^{31,114} Although the data are limited, combination regimens have been employed for patients with resistant strains or with respiratory failure. Peramivir is an available parenteral agent in the United States, and zanamivir is undergoing investigation or is available through emergency use authorization.³⁹ The use of moderate dosages of corticosteroids to reduce excessive inflammation is controversial but does not appear to result in worse outcomes.²³ There are limited data on whether other forms of immunosuppression should be lowered.

Prevention strategies for influenza center around strict infection control practices, including hand-washing, isolation, and eliminating potential exposures via universal vaccination of health care workers, patient family members, and caregivers. If a recent (<2 years or still immunocompromised) HSCT recipient has a significant exposure to a confirmed case of influenza, prophylactic administration of a neuraminidase inhibitor is recommended. This strategy also could be considered if a nosocomial outbreak was to occur on a HSCT unit.

Vaccination of HSCT recipients (with the inactivated strain) is highly recommended to occur for several years beginning at 6 months after HSCT, before which time the majority of adult patients are unlikely to mount a serologic response.³¹ Higher doses may be required to produce significant immunogenicity.⁸⁵ However, pediatric data are limited, and a fixed 6-month rule fails to take into account the significant variation in immunologic recovery times that occurs among patients depending on stem cell source and presence of GVHD. It is not unreasonable to allow earlier vaccination for patients on tapering doses of immunosuppression,^{108,231} even without documented B-cell function, because a T-cell response to influenza vaccine also may provide some protection.⁶ Finally efforts are under way to create influenza-specific T cells that can be given in a prophylactic fashion following HSCT.²²³

Respiratory syncytial virus. During seasonal outbreaks, upper respiratory tract infections from the RNA virus respiratory syncytial virus (RSV) are common in HSCT recipients. Approximately 50% of those infected will progress to involve the lower respiratory tract, especially in those with GVHD or severe lymphopenia.²¹³ A novel “immunodeficiency” scoring system can potentially be used to determine those patients at highest risk of progressing in the absence of therapy, while lower risk patients might spontaneously resolve. Untreated RSV pneumonia in HSCT recipients has a mortality rate as high as 75% to 80%.^{114,213} Ribavirin, a guanosine analog, is available in aerosolized form for the treatment of RSV. Several potential regimens exist, including a continuous 18-hour infusion and a 2- to 3-hour infusion given three times per day. Because of concerns about potential teratogenicity, it is usually administered in a scavenging tent. Respiratory side effects from inhaled ribavirin are common and include potential bronchoconstriction. Despite its problems and costs, a comprehensive review of inhaled ribavirin treatment in adult HSCT recipients suggests that initiation of ribavirin at the time of diagnosis of RSV upper respiratory tract infection can significantly decrease the risk for progression to lower respiratory tract disease and, in those with lower respiratory tract disease, can decrease the risk for death.²¹³ Antiviral therapy has the strongest effect in those with high-risk immunodeficiency scores, where RSV-associated mortality can potentially be lowered from 63% to 8%.¹¹⁴ An oral formulation of ribavirin (used for treating hepatitis C) and an intravenous formulation (not available in the United States) have also been used for treating RSV. Newer data suggest that this formulation may also be effective at preventing RSV-associated death, albeit with the risk of systemic side effects such as hemolytic anemia, lactic acidosis, and altered mental status.¹⁴²

Palivizumab, an RSV-specific monoclonal antibody, is effective at preventing RSV infections in very young high-risk children. Another potential immunomodulator is IVIG, which often contains anti-RSV antibodies and may decrease RSV-mediated cytokine-induced pulmonary inflammation. A review of the available studies of immunomodulation plus inhaled ribavirin suggests that the combination may be superior at preventing progression to lower respiratory tract disease and RSV-related death than inhaled ribavirin alone.²¹³ However, because of the small numbers, the report was unable to separate out those who specifically received palivizumab. Once lower respiratory tract disease is established, palivizumab has not been shown to improve outcomes.²¹⁰ As a result of the lack of any controlled trial, the use of the expensive

palivizumab has been questioned. Even more controversial is the prophylactic use of palivizumab. Fortunately the incidence of RSV infection in the first 100 days after HSCT is still relatively low at 5.8%.¹⁸⁰ However, based on decision tree analysis in children undergoing HSCT, it has been estimated that the use of prophylactic palivizumab may increase the absolute survival rate from 83% to 92%, suggesting that 12 children would need to be treated to prevent one RSV-related death.²³⁰ Clinical confirmation of this concept is lacking.

Even with “optimal” therapy of inhaled ribavirin plus an immunomodulator, the RSV-attributable mortality in HSCT recipients with lower respiratory tract disease is approximately 25%. Therefore improved treatments are desperately needed, and work is under way on higher affinity monoclonal antibodies, high-titer RSV immune globulin, and antisense compounds.²¹³

Other Respiratory Viruses

Other respiratory viruses, including parainfluenza virus,²²² human metapneumovirus,¹⁹² rhinovirus,¹⁶¹ and enterovirus D68,²⁵¹ have been implicated in causing lower respiratory tract disease in HSCT recipients. Risk factors for progression from upper respiratory tract infection to viral pneumonia include acquiring the infection early after HSCT, a low absolute lymphocyte count, and corticosteroid usage.²²² There is no FDA-approved antiviral agent with proved efficacy against these three viruses. However, identifying one of these viruses from the nasopharynx or bronchial washings can be useful in limiting empirical usage of potentially toxic agents to treat other infections, although these viruses often show up as co-pathogens. Some uncontrolled reports have suggested that inhaled ribavirin may be useful against parainfluenza³⁶; however, others have questioned its utility.¹⁷⁰ Recently a small case series has demonstrated possible efficacy of DAS181, an inhaled sialidase fusion protein, in HSCT recipients with severe parainfluenza infection.²⁵² Ribavirin has in vitro activity against human metapneumovirus, and a recent report suggests that ribavirin may play a role in helping resolve lower respiratory tract disease,²¹⁴ although controlled comparisons are lacking. Clearly, the best strategy for dealing with respiratory viral infections after HSCT is to avoid them through careful respiratory isolation.

Enteric Viruses

In addition to adenovirus, other enteric viruses such as rotavirus and norovirus, which typically cause self-limited disease in healthy individuals, can be major pathogens in HSCT recipients due to longer duration of symptoms and occasionally even death.^{130,198,208} Since profuse watery diarrhea may also be a symptom of gastrointestinal GVHD, careful exclusion of these viruses is critical in order to avoid potential over-treatment of that complication. Furthermore it has been suggested that these viruses may also be able to trigger the development of gastrointestinal GVHD.²⁴³ There is no specific antiviral agent for treating either virus, although enteral administration of immunoglobulin has been reported efficacious in a small case series.²⁵⁸ The antiprotozoal agent nitazoxanide has also been used with some activity against both viruses.²⁰⁰

Protozoa

Toxoplasma gondii

The majority of HSCT programs have dietary counseling in place that eliminates most undercooked meat; thus toxoplasmosis after HSCT is generally caused by reactivation of previously acquired cysts. Therefore serologic screening of HSCT candidates can identify most patients at potential risk (excepting those with deficient antibody production),¹⁴⁸ although reports of transmission from white blood cells do exist.¹⁰⁴ In seropositive patients, PJP prophylaxis with TMP-SMX also provides excellent coverage against toxoplasmosis.¹⁴⁸ Patients who cannot tolerate TMP-SMX need careful attention to the possibility of toxoplasmosis because most alternative PJP prophylaxis agents do not appear to provide sufficient protection.²³¹ A small study suggests that atovaquone may provide some protection;¹⁵⁶ alternatively clindamycin or pyrimethamine combinations can be used as either prophylaxis or preemptive treatment based on routine PCR screening for reactivation.^{196,231}

When toxoplasmosis occurs in a post-HSCT patient the general time frame is 2 to 6 months after HSCT. Because the brain is the most commonly affected organ, fever plus focal neurologic signs, headaches,

seizures, or altered mental status are the typical symptoms that should prompt evaluation for toxoplasmosis. Brain MRI may not always show the characteristic ring-enhancing lesions; therefore cerebrospinal fluid confirmation should be obtained.⁹⁹

Strongyloides stercoralis

Strongyloides stercoralis is endemic to the tropics and subtropics, including the southeastern United States. Transmission is usually via penetration of the larvae into exposed skin, from which it migrates into the intestines and possibly the lungs. HSCT candidates with intact immune systems may be asymptomatic or have only eosinophilia, and stool testing should be considered for anyone entering HSCT with elevated eosinophil counts, especially if they have traveled to or emigrated from an endemic area.¹⁰⁹ If positive, treatment with ivermectin is generally effective when disease burden is low. Infected individuals may begin to show evidence of disseminated disease within 1 to 3 months after HSCT. This “hyperinfection syndrome” can manifest as respiratory failure with diffuse pulmonary infiltrates, often with blood-tinged sputum, and/or colonic wall penetration, which leads to superinfection with gram-negative enteric organisms. Despite optimal treatment, mortality rates of hyperinfection syndrome are high.¹⁰⁰

Cryptosporidium parvum and C. hominis

Cryptosporidium spp. are enteric protozoa acquired from contaminated water supplies or livestock and infect intestinal epithelial cells. They cause seasonal transient nonbloody diarrhea and occasional systemic symptoms in healthy hosts and are frequently mistaken for a viral gastroenteritis. In immunocompromised HSCT recipients, however, cryptosporidiosis can cause a chronic severe diarrhea plus rare biliary tract disease. Multicenter incidence studies have never been performed, but, based on one single-center prospective study, it may be as high as 4% of all HSCT recipients and 10% of those with diarrhea.¹²⁴ Patients with B-cell deficiencies and CD40 ligand deficiency appear to be at especially high risk.¹²⁴ In HSCT recipients, the symptoms of a *Cryptosporidium* infection can easily be confused with that of intestinal GVHD, and testing for *Cryptosporidium* oocysts should be considered before initiation of additional immunosuppressants.¹²⁴ Therapy for *Cryptosporidium* is with paromomycin, azithromycin, or nitazoxanide. HSCT recipients may need combination therapy, and decreases in systemic immunosuppression should be performed when possible.¹²⁴

VACCINATIONS AFTER HEMATOPOIETIC STEM CELL TRANSPLANT

HSCT, especially from an allogeneic donor, involves the creation of a new immune system that lacks protective immunity in regard to vaccines received before the HSCT. Although some memory T and B cells may be passively transferred from the donor at the time of the cell infusion, the majority of the long-term immune system derives from newly generated naïve T and B cells. Therefore all HSCT recipients require revaccination after recovery of immune function. The major HSCT and infectious disease groups, plus the CDC, have published guidelines regarding the timing of vaccine administration,²⁰¹ but it has been argued that a “one size fits all” approach, as used in generally healthy infants, is insufficient to produce protective immunity in many HSCT recipients and that the vaccine schedule should be tailored to the individual kinetics of a patient’s T- and B-cell recovery and followed by titers to demonstrate adequate response.²¹⁹

Each year more than 500 children undergo heart transplantation around the world, and infection is an important cause of morbidity and some mortality in these patients.⁴⁴ The Registry of the International Society for Heart and Lung Transplantation (ISHLT) found that, from 2002 to 2012, infection (not including cytomegalovirus [CMV]) was the cause of death in pediatric heart transplant recipients in 8.5% of patients in the first year after transplant, 5.4% to 5.9% of patients 1 to 10 years posttransplant, and 5.5% of patients more than 10 years after transplantation.⁴⁴ Of the 9248 primary pediatric heart transplantations occurring between the years of 1998 and 2010 included in the ISHLT Registry, there were 3061 deaths, of which 9% were secondary to infection.²⁰²

The Pediatric Heart Transplant Study Group (PHTS) prospectively collected data from 22 pediatric centers in the United States from January 1993 to December 1994 on 332 children younger than 18 years (mean age, 5.5 years) who had undergone heart transplantation.¹⁶⁹ One or more infections (276 total) occurred in 41% of the patients (mean follow-up time, 11.8 months) for an average of 0.84 infections per patient; 22% had one infection, 8% had two infections, and 11% had three or more infections during the study period (Table 70.1). In an updated report from this multicenter group summarizing children who had undergone heart transplantation over the decade starting in 2000, 72% were free from infection at 1 year posttransplant.⁴³ In a similar multicenter study in adults who had undergone heart transplantation between January 1990 and June 1991, infections developed in 31% of 814 patients, with 22% having one infection and 9% having two or more infections.¹³⁵

Bacterial infections were the most common type of infection occurring after transplantation in pediatric and adult patients. PHTS reported that 54% of 2038 infections in 1220 patients from January 1993 to December 2004 were bacterial, 32% were viral, 7% were fungal, 0.5% were protozoan, and 7% were unknown.²¹⁶ One single-center retrospective review of pediatric patients who underwent heart transplantation and who survived a minimum of 5 years after transplantation reported that infant transplant recipients had an increased risk of serious bacterial infections per 10 years of follow-up (mean, 2.04 ± 0.5) and chronic or recurrent bacterial infections (mean, 4.58 ± 0.67) compared with older recipients (means, 0.37 ± 0.19 and 1.87 ± 0.70 , respectively).¹¹⁰ Risk factors for an infectious cause of death in pediatric heart transplant recipients include pretransplant factors such as use of pretransplant extracorporeal membrane oxygenation (ECMO), presence of pretransplant infection, diagnosis of congenital heart disease, higher pretransplant creatinine, and higher sensitization levels as well as any cardiac reoperation prior to discharge and positive donor CMV serology.²⁰²

From 2009 to June 2014, ISHLT reported that 68% of children who underwent heart transplantation received induction immunosuppression, most commonly with antithymocyte globulin (47%) or interleukin-2 (IL-2) receptor antagonist (24%). Maintenance immunosuppressive therapy after transplant included a combination of a calcineurin inhibitor (tacrolimus in 84% and cyclosporine in 15%), an antimetabolite (mycophenolate mofetil or mycophenolic acid in 91% or azathioprine), and prednisone (70%). At 5 years posttransplant, 96% of patients were on a calcineurin inhibitor, 75% were on an antimetabolite, 36% were on a steroid, and 19% were on a mammalian target of rapamycin (mTOR) inhibitor (such as sirolimus).⁴⁴ Calcineurin inhibitors predominantly block the effect of IL-2 on T cells, an action resulting in a diminished T-cell response to mitogen stimulation.⁷⁶ The infections seen in heart transplant patients outside the postoperative period generally are a result of this block in T-cell function. Because the types of infections seen in these patients vary with the time elapsed since transplantation, this chapter is organized in such a manner.

PRETRANSPLANTATION EVALUATION

Several infectious agents may be transmitted to the patient via the transplanted organ or can become “reactivated” after transplantation. Determining the antibody status of the recipient and the donor against selected microorganisms (CMV, Epstein-Barr virus [EBV], *Toxoplasma gondii*) helps physicians anticipate, prevent, and diagnose infections that develop after transplantation. A reasonable pretransplant evaluation for children is outlined in Box 70.1 but varies depending on the patient’s history and geographical location. The child’s immunization status is documented, and vaccinations are completed when possible (i.e., hepatitis B vaccine, *Haemophilus influenzae* type b, or *Streptococcus pneumoniae*). The Committee on Infectious Diseases of the American Academy of Pediatrics recommends that candidates for solid organ transplantation should receive all vaccinations as appropriate for age, exposure history, and immune status.⁷ The 23-valent pneumococcal polysaccharide vaccine (PPSV23) should be given to patients 2 years of age or older at least 8 weeks after the last 13-valent pneumococcal conjugate vaccine has been administered. If possible, appropriate vaccines should be administered at least 1 month before the patient undergoes transplantation. Evidence of selected active infections is a contraindication for transplantation. Chemoprophylaxis should be considered strongly for children with a positive tuberculin skin test (purified protein derivative). Dental status also is assessed.

In addition to having the routine pretransplant evaluation as outlined in Box 70.1, each patient should be screened carefully for selected infections appropriate to the individual circumstances. If surgery is planned during the respiratory disease season and the patient has respiratory symptoms just before having surgery, screening for influenza virus or respiratory syncytial virus (RSV) by rapid techniques may facilitate prescribing antiviral therapy postoperatively. In areas where community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) is an important cause of infection, performing surface cultures to detect MRSA colonization may modify the choice of antibiotics used for surgical prophylaxis.⁹⁷ Providing mupirocin intranasally as well as employing chlorhexidine baths preoperatively may decrease the rate of postoperative MRSA infections in patients colonized with MRSA.^{71,142} In areas where coccidioidomycosis is endemic or for the patient with travel to endemic areas, pretransplant serology for *C. immitis* is recommended, and, if positive, antifungal prophylaxis is provided.²⁰³ Screening for histoplasmosis is not recommended, but itraconazole prophylaxis may be considered for patients with recent history of active histoplasmosis infection.^{38,134} Children from resource-poor countries may harbor *Salmonella* or intestinal parasites asymptotically, and these organisms can cause serious infection after the child undergoes transplantation. Preoperative stool cultures for enteropathogens and examination of the stool for parasites may alert the clinician that these pathogens are present and could be the etiology of postoperative infections. Screening for *Strongyloides* is recommended for recipients in endemic areas or for patients with unexplained eosinophilia prior to transplant, and patients who are positive should be treated with ivermectin prior to transplantation.³⁷

If the patient is being mechanically ventilated before undergoing transplantation, review of recent tracheal aspirate cultures may help in the selection of empirical antibiotics for initial treatment of suspected nosocomial sepsis or pneumonia. Pretransplant infections associated with procedures such as implantation of ventricular assist devices may require prolonged antibiotic therapy after transplantation is performed.^{122,181} Intraoperative cultures of involved tissues including the mediastinum as well as various surfaces from the device should be obtained and the results guide therapy.¹⁰⁷ These infections typically are

BOX 70.1 Evaluation of Children Before Heart Transplantation

- Serology:
- Cytomegalovirus^a
 - Epstein-Barr virus
 - Coccidioidomycosis^b
 - Toxoplasma gondii*
 - Strongyloides^c
 - Human immunodeficiency virus
 - Hepatitis A, B, and C
 - Herpes simplex virus
 - Parvovirus^d
 - Rubeola, mumps, rubella, varicella^e
 - Syphilis^f
- Cultures:
- Nasopharyngeal, stool, or tracheal aspirates^g
- Skin tests:
- Tuberculin skin test^h
- Consider freezing of an extra aliquot of serum
- Review of the child's immunization status

^aUrine CMV PCR for children <18 months rather than serology because maternal antibody may still be present.¹⁵³
^bDepends on geographic regions patient has lived in or traveled to.
^cIf from an endemic area or has eosinophilia.
^dMay help with interpretation of molecular tests of endomyocardial biopsies.
^eFor children >12 months and previously immunized.
^fDepends on age and history.
^gSee text for an explanation.
^hInterferon-γ release assay may be helpful in selected cases.¹⁹⁴

caused by common nosocomial pathogens and are not a contraindication to undergoing heart transplantation. The reader is referred to more detailed discussions of the pretransplant assessment of the donor and recipient.⁶⁰

SURGICAL PROPHYLACTIC ANTIBIOTICS

Prophylactic antibiotics typically are administered to patients undergoing heart transplantation surgery. For each institution, selection of prophylactic antibiotics should be based partly on the organisms isolated from postoperative wound infections in that center and the antimicrobial

susceptibility of these organisms. Cefazolin is generally considered the drug of choice for perioperative prophylaxis. If MRSA is a nosocomial pathogen of concern or if the transplant recipient is colonized with MRSA, a single dose of vancomycin, in addition to cefazolin, is suggested. Both vancomycin and cefazolin are recommended because data suggest that vancomycin is less effective than cefazolin for preventing surgical site infections caused by MSSA.²³ Routine use of extended-spectrum cephalosporins is discouraged because it may lead to colonization of the patient by fungal organisms or antibiotic-resistant, gram-negative organisms that hyperproduce β-lactamase, such as *Enterobacter cloacae*. Expert guidelines recommend prophylactic antibiotics should not be administered beyond 48 hours post heart transplantation as part of a strategy to prevent the development of multidrug-resistant gram-negative bacteria and fungal pathogens.²⁰¹

IMMEDIATE POSTOPERATIVE INFECTIONS

Common Infections

During the month after the patient undergoes heart transplantation, the types of infections encountered are the same as those complicating major thoracic surgery. Nosocomially acquired bacteria are the most common causative pathogens, and the incidence of multidrug-resistant organisms is increasing.⁴⁷ Pneumonia and bacteremia are the most common postoperative infections. The frequency of bacteremia and the distribution of organisms are similar in children and adults after undergoing heart transplantation.^{135,169} In the PHTS study, the risk of development of any infection was 25% 1 month after transplantation. Overall 60 episodes of bacteremia occurred in the 136 patients who became infected, and the bloodstream was the most common site of bacterial infection.¹⁷⁰ Lung abscesses and mediastinitis are seen less frequently. Familiarity with the organisms and the antimicrobial susceptibility of isolates recovered from other children in the ICUs in which these patients receive care helps direct the initial empirical selection of antibiotics.

Postoperative bacteremia is related predominantly to the indwelling lines required for monitoring and infusion of medication. *S. aureus*, coagulase-negative staphylococci, *Enterococcus* spp., and gram-negative enteric organisms such as *Enterobacter* spp., *Pseudomonas aeruginosa*, *Klebsiella* spp., and *Escherichia coli* are the most common causes of nosocomial bacteremia in the pediatric ICU.^{90,130,158} Other foci of infection, such as pneumonia, mediastinitis, or urinary tract infection also may result in bacteremia in heart transplant patients.^{160,205} Vancomycin plus an extended-spectrum penicillin, third- or fourth-generation cephalosporin, or an aminoglycoside is a typical empiric antibiotic combination for suspected bacteremia in patients with central lines in place and without focal evidence of infection. Antibiotics are modified based on the organism(s) isolated and the antimicrobial susceptibilities of the isolate. Vancomycin therapy should be discontinued as soon as possible if an organism requiring the administration of vancomycin is not isolated.¹⁵⁵ A bacterial line infection may be eradicated successfully without removing the line, but the line should be removed if blood cultures remain positive or the patient's clinical condition deteriorates.¹³² Optimally central lines are removed for *S. aureus* central line–related bloodstream infections.³⁰ Fungemia, generally with *Candida albicans* or other *Candida* spp., also may be associated with line-related infections. Central lines complicated by fungemia should be removed immediately.^{56,132} *Candida* infections following heart transplantation are not frequent enough to warrant routine prophylaxis, but they are associated with mortality rate of up to 48% in pediatric heart transplant recipients.^{180,216}

As in other critically ill children, pneumonia is a particularly common occurrence in heart transplant patients because of the operative site and requirements for intubation and mechanical ventilation. During the first postoperative week, definite bacterial pneumonia developed in three of 22 children (14%) in an early study from the University of Pittsburgh Medical Center (UPMC).⁸⁰ In the PHTS study, 56 bacterial lung infections were identified, 24 of which developed in patients maintained on a ventilator at the time of transplantation.¹⁶⁹ The incident rate of early nosocomial pneumonia in adult heart transplant patients has been reported to be 20% to 35%.^{11,34} Nosocomial pneumonia caused

by gram-negative bacilli such as *Pseudomonas* and *Enterobacter* or *S. aureus* is especially common in this setting.¹⁵⁸ Gram stain and culture of a tracheal aspirate or bronchoalveolar lavage (BAL) can help guide therapy for pneumonia.

A broad-spectrum combination of antibiotics, such as an extended-spectrum penicillin with a β -lactamase inhibitor (i.e., piperacillin-tazobactam) plus an aminoglycoside, usually is initiated until a pathogen or pathogens are identified. Empirical therapy should be based on the antibiotic susceptibility patterns of the common nosocomial pathogens in the specific ICU in which the patient is receiving care. Vancomycin also should be considered if MRSA is part of the resident flora in the ICU. Computed tomography (CT) of the chest may detect basilar and retrocardiac pneumonia, which may not be visualized readily by conventional chest radiographs. CT or ultrasound generally is helpful in assessing the size or characteristics of pleural effusions that may require drainage.

If interstitial pneumonitis is encountered, a more aggressive approach to determining an etiology is warranted. Bronchoscopy with BAL should be considered strongly. Lavage fluid is processed for pathogens including bacteria, mycobacteria, viruses, fungi, and protozoa by using culture techniques, special stains, and molecular techniques such as quantitative PCR. Mini-BAL are commonly employed in some pediatric centers, but how their results compare to a formal BAL procedure is not clear and has not been well studied in children.⁶⁶ *Legionella* may be an important consideration in some centers.^{22,156} Noninfectious causes of pulmonary infiltrates in these children include pulmonary edema, atelectasis, hemorrhage, and acute respiratory distress syndrome.

Urinary tract infections (UTIs) also are common occurrences in the month after undergoing heart transplantation. Urinary catheterization and the immunosuppressive agents contribute to the risk for developing a UTI. Gram-negative enteric organisms (*E. coli*, *K. pneumoniae*, *P. aeruginosa*, and *Enterobacter* spp.), enterococci, and *Candida* spp. are isolated most commonly. Removal of the catheter as soon as possible minimizes the potential for development of a UTI, which has occurred in approximately 10% of adults. In the PHTS study, the urinary tract was the site of 16 bacterial infections.¹⁶⁹ In addition, UTIs developed in three children (14%) at UPMC during the 2 to 3 weeks after undergoing transplantation.⁸⁰

The broad-spectrum antibiotics used to treat the bacterial complications of transplantation promote *Candida* infection of the urinary tract. Along with removal of the urinary catheter, short-course intravenous amphotericin B or fluconazole with careful dosing because of drug interactions with tacrolimus and cyclosporine is an option for treating candidal cystitis.¹⁴⁶ In some patients, especially infants, a urine culture positive for *Candida* is a clue that a disseminated *Candida* infection is present and that further investigation, including imaging, is necessary to exclude the involvement of other organs, especially the kidneys.

Antibiotic-associated diarrhea caused by *Clostridium difficile* is another potential complication related to antibiotics administered both pre- and posttransplant.^{20,48} Toxic megacolon due to fulminant *C. difficile* infection requiring subtotal colectomy has been reported in a 10-year-old within 1 week after undergoing heart transplantation.¹⁴⁷

Risk factors for early infection in the PHTS study were younger recipient age (particularly less than 6 months), mechanical ventilation at the time of transplantation, positive donor CMV serology with a CMV-negative recipient, and longer donor ischemic time.¹⁶⁹ Although primarily conducted among adult liver transplantation patients, studies have shown measuring procalcitonin may help distinguish infection from other causes of fever following solid organ transplantation.²¹⁴ Studies in adult heart transplant patients have shown that elevated procalcitonin levels beyond the first week after transplantation are correlated with infectious complications and that the use of serial procalcitonin measurements may be more reliable than single values.^{166,190}

Sternal Wounds and Mediastinitis

Sternal wound infections and mediastinitis occur in less than 5% to 15% of adult heart transplant recipients compared with less than 5% of adult patients receiving general cardiac surgery.^{29,59,99,135,136,174,218} Most of these infections occur during the first postoperative month, usually within the first 2 weeks, and are superficial. The majority of surgical

site infections are caused by bacteria. Staphylococci and other gram-positive bacteria generally are responsible for 50% of cases, and the remainder are caused by a variety of gram-negative bacilli.¹³⁸ Higher incidences of fungal pathogens have been reported in heart transplant recipients compared with general cardiac surgery patients.²¹⁸ Surgical wound infections developed in eight children in the PHTS study, although the site of the infection was not noted.¹⁶⁹ Over a 15-year period, 15 (0.2%) children at Texas Children's Hospital (TCH), Houston, Texas, developed mediastinitis after undergoing cardiac surgery; two children had undergone heart transplantation.¹⁹⁵ At another children's hospital, between 1995 and 2003, 3% (5 of 165) of children undergoing heart and lung transplantation developed mediastinitis.¹¹⁶

Risk factors for surgical site infections in adult heart transplant recipients include body mass index greater than 30 kg/m², previous heart surgery, previous ventricular assist device implantation, inotropic support, and prolonged cardiopulmonary bypass time.⁴⁷ Immunosuppression regimens that include sirolimus have been identified as a risk factor for surgical site infection, wound dehiscence, and mediastinitis.^{111,217} Postoperative bleeding requiring reexploration is also a risk factor for the development of mediastinitis. Fever, incisional pain, and an unstable sternum suggest mediastinitis; however, patients may have no specific evidence of infection, including fever. The white blood cell count may be elevated. A pericardial effusion frequently is detected with the development of mediastinitis, and pericardiocentesis may yield purulent material. CT of the chest may show a fluid collection or abscess within the mediastinum and can detect sternal osteomyelitis. Most cases of mediastinitis are caused by *S. aureus*, coagulase-negative staphylococci, or gram-negative bacteria. Median sternotomy wound infections after repair of a congenital heart lesion occur in less than 1% of children in large centers. Mediastinitis caused by gram-negative bacilli in association with pneumonia and bacteremia developed in three of the 22 children in the UPMC series; each occurred within 2 weeks postoperatively.⁸⁰ Two of the three patients died. *Candida* spp. caused both cases of mediastinitis in the two children after heart transplantation in the TCH series.¹⁹⁵ Long and colleagues¹¹⁶ reported that mediastinitis developed in five patients who had undergone heart and lung transplantation and that the organisms identified in these children were *E. coli*, *Torulopsis glabrata*, *Aspergillus fumigatus*, *Burkholderia cepacia*, and vancomycin-resistant enterococcus.

A superficial median sternotomy wound infection not associated with an unstable sternum can be treated by local drainage of the infected subcutaneous tissue and administration of appropriate antibiotics.⁵¹ Vacuum-assisted closure may be an important aid in addition to antibiotics.¹ A more aggressive approach is required for more serious infections associated with an unstable sternum, mediastinitis, or osteomyelitis of the sternum.^{28,51,99} Adequate drainage and debridement of the area are crucial, and any involved wires should be removed. Mediastinal drains usually are kept in place for several days. A reoperation after the initial drainage procedure may be necessary. Pending culture results, antibiotic therapy is directed against *S. aureus* and gram-negative bacilli. A 4- to 6-week course of antibiotics usually is recommended. Antifungal therapy is initiated if a yeast or fungus is noted on Gram or special stains or isolated from cultures. Careful attention given to surgical technique to minimize postoperative bleeding and early withdrawal of chest and mediastinal tubes placed intraoperatively decrease the incidence of these potentially fatal infections.

Other Infections Encountered During the First Postoperative Month

Herpes Simplex

Herpes simplex infections of the oral mucosa and other superficial surfaces are common after heart transplantation. Oral herpes simplex was observed in 21% (11 of 53) of children undergoing transplantation at Stanford University Medical Center.¹⁵ In the pediatric multiinstitutional PHTS study, only six episodes of herpes simplex infection were noted.¹⁶⁹ Visceral involvement is unusual, although it may develop.¹¹² Herpes simplex infection typically occurs approximately 13 days (range, 0 to 4 months) after transplantation and is secondary to reactivation, not a newly acquired infection.¹⁵² A decrease in lymphocyte transformation

in response to viral antigen in vitro may explain the increased rate of infection that occurs in the first 12 weeks posttransplantation. In a large randomized study comparing azathioprine with mycophenolate mofetil in adult heart transplant recipients who also were receiving cyclosporine and steroids, herpes simplex infection occurred more commonly in the group treated with mycophenolate mofetil (23% vs. 16%; $P < .05$).⁵² Institution of antiviral therapy for herpes simplex infection is warranted in these immunocompromised patients. The most common antiviral agent for herpes simplex is acyclovir, which can be administered orally or intravenously. Valacyclovir dosing in children has been established for children older than 2 years, but a commercial suspension is unavailable.

Prophylactic acyclovir is recommended by some experts for heart transplant recipients who are seropositive for herpes simplex.^{75,211} Acyclovir can be given intravenously during the perioperative period and then orally for at least a month following transplantation. Other physicians suggest that because labial or oral herpes simplex is treated so easily, a prophylactic approach after transplant is not warranted. Prophylaxis is generally used during treatment for rejection and for prolonged durations if recurrences are frequent. If the patient is receiving ganciclovir for CMV prophylaxis, additional HSV preventive measures are not necessary.

Legionella pneumophila

Legionella pneumophila infection should be included in the differential diagnosis for fever, respiratory symptoms, and pulmonary infiltrates that develop after heart transplantation.³³ *Legionella* pneumonia can develop during the first postoperative month, but the frequency with which this infection occurs varies among transplant centers. Although legionnaires' disease is an uncommon occurrence in children, nosocomial infections have been documented in a children's hospital, and immunosuppression is a risk factor.^{22,27} Appropriate cultures and direct fluorescent antibody stains for *Legionella* should be performed on sputum, other respiratory secretions (obtained by invasive techniques), pleural fluid, or lung tissue to detect this pathogen in a timely fashion. A *Legionella* urinary antigen test is available for serogroup 1 antigens and is quite sensitive.¹⁹²

Macrolides should be considered for empiric therapy if *Legionella* is a serious consideration in children with nosocomial pneumonia. A 2-week course of erythromycin or azithromycin is generally recommended. Macrolides interact with many of the immunosuppressive agents administered to these patients, however. Quinolones also are quite active against *Legionella* and avoid many of these interactions; in adult transplant patients, levofloxacin is the agent of choice.¹⁹² The use of quinolones should be considered for pediatric organ transplant recipients in whom infection with *L. pneumophila* is suspected. In hospitals caring for patients with transplants, routine surveillance culture of the hospital water supply should be considered.

Respiratory Syncytial Virus

Ten episodes of RSV infection were noted in the multiinstitutional study by the PHTS Group.¹⁶⁹ RSV can be acquired in the hospital soon after undergoing transplantation or can be acquired in the community before undergoing surgery or after discharge. Too few patients in whom RSV infection developed after they underwent heart transplantation have been described to comment on the clinical features. Two children in the early UPMC study were noted to be infected with RSV, both infections occurring on postoperative day 10. Rapidly progressive patchy infiltrates on chest radiographs developed in one child after undergoing heart-lung transplantation, and the second child had only mild upper respiratory symptoms.⁸⁰ Tachypnea, cough, fever, wheezing, and the use of accessory muscles occurred commonly in the 18 pediatric liver transplant recipients from UPMC with RSV infection.¹⁵¹ Radiographic changes included interstitial and lobar infiltrates, atelectasis, and pleural effusion in 12 patients. Two patients required mechanical ventilation after the onset of symptoms related to RSV infection occurred; three others were intubated before acquiring RSV infection and subsequently had complicated courses. At Boston Children's Hospital, there were 34 RSV infections in 851 solid organ transplant recipients from 1993 to 2006. Two deaths were reported: a 1-year-old with RSV 2 days after

renal transplant and an 18-year-old 776 days after liver transplant who also had disseminated aspergillosis.¹¹⁵

Morbidity and mortality rates related to RSV infection are increased in otherwise immunocompetent children with congenital heart disease, especially when associated with pulmonary hypertension.¹²⁰ Because RSV can be acquired in the hospital, RSV infection should be considered in a young transplant patient with respiratory symptoms and fever, especially during the RSV season.⁸² RSV infection is documented by culture or by rapid detection of RSV infection by a variety of techniques.

The decision to administer ribavirin to these patients is based primarily on the severity of the illness. In a small group of children with underlying bronchopulmonary dysplasia or congenital heart disease, aerosolized ribavirin seemed to be associated with more rapid improvement than that in patients given placebo.⁸³ Administration of aerosolized ribavirin to a heart transplant recipient with proved or suspected moderate to severe RSV infection is reasonable. As is the case with children requiring mechanical ventilation because of severe RSV lower respiratory tract infection, however, the efficacy of ribavirin in this situation is unknown.¹⁸⁵ The 2015 *Red Book* states that "ribavirin ... may be considered for use in select patients with documented, potentially life-threatening RSV infection."⁸

The monoclonal antibody palivizumab was found to be safe, well tolerated, and effective in preventing serious RSV infections in young children with hemodynamically significant congenital heart disease in a large multicenter randomized, double-blind, placebo-controlled trial.⁵⁸ Palivizumab administration to children 24 months or younger who have undergone heart transplantation is reasonable, especially in children who are on medications for heart failure or pulmonary hypertension.⁵ The combination of ribavirin and RSV immunoglobulin has been administered to pediatric bone marrow transplant recipients with RSV lower respiratory tract infection.⁴² The outcome in these patients was improved over that of historical controls, but no randomized trials have been conducted. RSV immunoglobulin was not efficacious in treating RSV lower respiratory tract infection in children with congenital heart disease who were younger than 2 years.¹⁵⁹ Although palivizumab reduced the concentration of RSV in the tracheal aspirates of children with respiratory failure caused by RSV, its efficacy in treatment is unknown.^{92,123} Many authorities recommend both ribavirin and an antibody product for the management of severe RSV infections in solid organ transplant patients.¹²⁵

INFECTIONS BETWEEN THE FIRST AND SIXTH POSTOPERATIVE MONTHS

Cytomegalovirus

CMV is the most frequently identified viral infection in cardiac transplant patients. Asymptomatic or symptomatic infections are noted most commonly between the first and sixth months after undergoing transplantation but can occur late after transplant.¹⁹ In adult series, the majority of patients have developed CMV infection at some time postoperatively.^{50,78,135,187} In the multiinstitutional PHTS study, 51 episodes of CMV infection occurred in 332 patients and accounted for 60% of the viral infections, with a peak occurrence in the second month after transplantation.¹⁶⁹ CMV infection occurred more frequently in older children than in infants. In another study, infants younger than 120 days had CMV infection and disease less commonly than did infants older than 120 days after undergoing heart transplantation.⁶⁷ Maternal antibody to CMV may have been protective in the younger infants. In the UPMC series, seven children (32%) had CMV infections, with onset occurring at a mean of 33 days posttransplant (range, 23 to 43 days).⁸⁰

CMV infection in transplant recipients occurs in three or four possible settings. In a seronegative recipient, primary CMV infection is acquired through the transplanted heart, through blood transfusions from seropositive donors, or from community exposure. Seropositive recipients can have reactivation of latent CMV infection or be reinfecting with a second strain of CMV from the heart or from blood products derived from seropositive donors.^{32,24} The exact site within the donor heart where CMV may reside in a latent form is unknown, but it may be either cardiac cells or leukocytes that remain within the donor heart.

When primary CMV infection is acquired from the donor organ, CMV disease tends to be more severe than if CMV infection is acquired from blood or blood products.²¹²

Several risk factors for development of CMV infection after undergoing organ transplantation are recognized. Donor and recipient serologic status and the immunosuppressive regimen are the most significant risk factors for acquiring CMV infection after undergoing heart transplantation. Gorenshek and colleagues⁷⁸ found that positive recipient CMV serology before transplantation and a larger than average dose of corticosteroids were significant risk factors for acquiring CMV infection. Among the group of patients with CMV infection, positive recipient serology was associated with asymptomatic infection, and excessive steroid dosing was a risk factor for acquiring symptomatic CMV infection. CMV tissue invasion occurred more commonly in patients receiving mycophenolate mofetil compared with azathioprine. Use of lymphocyte-depleting agents such as antilymphocyte antibodies increases the risk of CMV disease.¹⁵³

The clinical manifestations of CMV infection vary. Patients may seroconvert or a latent infection may be reactivated, as determined by positive cultures or molecular tests, but these patients have no symptoms attributable to the CMV infection. Fever, leukopenia, and thrombocytopenia are common postoperative manifestations of systemic CMV infection. Patients may complain of arthralgias, myalgias, and nonspecific abdominal pain. Atypical lymphocytes are noted more commonly in adult than pediatric patients. CMV infection can cause hepatitis, pneumonitis, retinitis, myocarditis, and gastrointestinal disease, including colitis.^{50,57,61,77,78,98,179} Invasion of organs, especially the gastrointestinal tract, can occur in the absence of detectable CMV in the blood. Retinitis may be asymptomatic or associated with complaints such as floaters or scotomata. Ophthalmologic screening for CMV retinitis is recommended by some authorities for all patients 3 to 4 months after cardiac transplantation.⁶¹

Of the tissues invaded by CMV, involvement of the lung leads to the greatest mortality rate—13% in one study.¹⁰³ CMV pneumonitis is characterized by fever, hypoxemia, and, usually, diffuse interstitial infiltrates, although lobar consolidation may occur.¹⁷⁸ Pulmonary infections with other viruses or with bacteria or *Pneumocystis jirovecii* and other pathologic processes (infarction) may coexist with CMV pneumonitis. Gastritis, gastric ulceration, duodenitis, esophagitis, pyloric perforation, and colonic hemorrhage can be documented by endoscopy. In the multiinstitutional PHTS study, the lung or gastrointestinal tract was the site of CMV infection in 13 (lung) and six (gastrointestinal tract) episodes.⁸⁰ Death related to CMV in the pediatric study occurred in 6%. In another pediatric heart transplant registry spanning 1998 to 2010, CMV was considered the cause of death in 2.7%, 0.4%, and 0.4% of patients 31 days to 1 year, after 3 to 5 years, and after 10 years post transplantation, respectively.¹⁰² In another analysis using a multiinstitutional registry of pediatric heart transplantation patients, clinical CMV infection was uncommon in the setting of antiviral and/or CMV antibody prophylaxis.¹²¹

Serology is not recommended for establishing the diagnosis of CMV infection after transplantation.¹⁰⁶ Viral load testing by quantitative nucleic acid amplification testing (QNAT), which is the preferred test, or CMV antigenemia is recommended for the diagnosis and monitoring for CMV infection and disease.¹⁰⁶ Whether the CMV infection is causing a symptomatic or invasive illness is more difficult to establish. Histopathologic evidence of CMV infection, such as typical viral inclusions or detection of antigen in tissue by special stains, is required to confirm organ involvement by CMV, although this criterion often is not considered for clinical management and treatment.

In addition to the CMV infection syndromes, CMV infection itself seems to affect the transplant recipient adversely in other ways. Symptomatic or asymptomatic CMV infection is associated with a higher rate of acute rejection and graft loss, a greater risk of development of fungal infection, more frequent and earlier cardiac allograft vasculopathy, and a significantly lower survival rate than occur in patients who do not have CMV infection.^{41,63,94,162} In the PHTS study, CMV-positive donor serology in conjunction with CMV-negative recipient serology was a risk factor for the acquisition of earlier infection with any organism.¹⁶⁹

CMV infection of the wide variety of cells that it invades leads to the activation of protein synthesis and the production of multiple immunologically active molecules, including cytokines, especially tumor necrosis factor- α , which adds to the immune deficits induced by the immunosuppressive agents.^{63,105} Allograft injury or rejection may be associated with CMV infection of the transplanted organ itself.⁶³

Successful treatment or suppression of visceral CMV disease by ganciclovir, a nucleoside analogue active in vitro against CMV, requires a timely diagnosis. Ganciclovir has been shown to alter CMV disease favorably in heart transplant patients, along with reduction in immunosuppressive therapy when possible.¹⁰⁰ The recommended length of therapy is determined by weekly monitoring of CMV viral loads and continuing therapy until 1 or 2 consecutive negative samples. The minimum course of therapy is 2 weeks. The dose of ganciclovir is 5 mg/kg every 12 hours with careful monitoring of hematologic parameters and renal function if renal function initially is normal. Modification of the dose is necessary if renal function is impaired. The most common adverse reactions to ganciclovir are neutropenia, thrombocytopenia, impaired renal function, seizures, and other central nervous system (CNS) abnormalities. Many experts will use oral valganciclovir instead of intravenous ganciclovir in nonsevere CMV disease. Some transplant centers will use secondary prophylaxis with once daily oral valganciclovir for 1 to 3 months after completion of therapy for CMV infection.¹⁰⁶

The role of CMV hyperimmunoglobulin in treating CMV infection in these patients requires further study. After bone marrow transplantation, the addition of CMV immunoglobulin to ganciclovir may be superior to ganciclovir alone in treating CMV pneumonia.^{55,157}

In one pediatric study, symptomatic CMV disease developed in five children after they had undergone heart transplantation; each had blood cultures and PCR positive for CMV.⁶⁹ Four were treated with ganciclovir for 14 days; one received ganciclovir for 30 days. All received CMV-IgG (150 mg/kg) weekly for 3 weeks. Symptomatic CMV disease was treated successfully in each case. CMV-IgG may be beneficial in treating life-threatening CMV disease such as pneumonitis and enteritis.^{106,153} For CMV disease in thoracic organ transplant recipients with hypogammaglobulinemia, intravenous immunoglobulin or CMV-IgG is recommended as adjunctive therapy as well.¹⁰⁶

If possible, prevention of CMV infection in heart transplant recipients is optimal. Only seronegative blood should be used for transfusions when the recipient and the donor are seronegative. Careful control of immunosuppressive therapy, especially with corticosteroids, may help avoid the acquisition of some infections. Prophylactic administration of intravenous ganciclovir followed by oral valganciclovir for 3 to 6 months appears to be the strategy of choice for preventing CMV infection in adults at risk following heart transplantation.^{106,153} The updated CMV consensus statement recommends 3 to 6 months for adult patients who are CMV seronegative and receive a heart from a CMV seropositive donor; 3 months is recommended if the recipient is CMV seropositive regardless of the donor's status.¹⁰⁶ The longer duration is determined in part by the degree of immunosuppression required. The duration of prophylaxis in children is not as well established and varies among centers. In the situation of a seronegative recipient of a heart from a seropositive donor, the addition of prophylactic administration of CMV immunoglobulin to ganciclovir may be useful.^{2,154,186} If the prophylactic approach is used, routine monitoring for CMV viral load is not recommended but should be evaluated if patients have symptoms that could be caused by CMV infection.¹⁰⁶

In one large randomized double-blind, placebo-controlled trial of CMV-seropositive transplant recipients, ganciclovir significantly reduced the incidence of CMV illness during the first 120 days after heart transplantation (9% vs. 46% in controls; $P < .001$).¹³¹ No differences were noted between the study groups for seronegative recipients.

Whether the addition of CMV-IgG to antiviral therapy for prophylaxis of high-risk seronegative recipients of hearts from seropositive donors results in added benefits is still under investigation. Avery¹² found that the combination was not particularly effective; symptomatic CMV syndrome developed in 50% of patients. Gajarski and associates⁶⁹ provided CMV-IgG (150 mg/kg intravenously at weeks 0, 2, 4, 6, and 8 and 100 mg/kg intravenously at weeks 12 and 16) plus ganciclovir (5 mg/kg every 12 hours intravenously for weeks 1 and 2 and 6 mg/kg

per day intravenously at weeks 3 and 4) to 19 children who were recipients of heart transplants from CMV-seropositive donors. CMV disease occurred in three of the 10 children who were CMV-seronegative and in one of the 10 recipients who were seropositive. Adverse effects of these agents were not reported. In the study from Stanford University Medical Center, high-risk recipients received CMV-IgG immediately after undergoing transplantation (150 mg/kg administered within 72 hours after transplantation, followed by 100 mg/kg at weeks 2, 4, 6, and 8 and 50 mg/kg at weeks 12 and 16).^{199,200} In addition, ganciclovir was administered intravenously immediately after transplantation at a dose of 5 mg/kg every 12 hours for 14 days, followed by 6 mg/kg per day for the next 2 weeks. These patients were compared with a historical control group at the same institution that received ganciclovir in the 2 to 3 years before CMV-IgG was used. The 27 recipients treated prophylactically with ganciclovir and CMV-IgG had a higher disease-free incidence of CMV, a lower incidence of rejection, and a higher survival rate than those of the historical cohort treated with ganciclovir alone. Data from the Scientific Registry of Transplant Recipients indicated that, for children undergoing heart transplantation, CMV immune globulin with or without ganciclovir and ganciclovir with or without CMV immune globulin were associated with significant reduction in graft loss and deaths versus no prophylaxis.¹⁸⁶ Immunologic monitoring of CMV may be helpful in assessing the risk of patients developing CMV viremia and disease posttransplantation, although the value of this monitoring is unknown in children.¹⁰⁶

CMV resistant to ganciclovir may emerge as a result of ganciclovir prophylaxis or treatment.^{14,101} Foscarnet or cidofovir is an alternative agent in this situation. The reader is urged to review the "Updated International Consensus Guidelines on the Management of Cytomegalovirus in Solid-Organ Transplantation" document for expert guidance on this subject.¹⁰⁶

Epstein-Barr Virus

In pediatric heart transplant recipients, EBV may cause a spectrum of diseases, including a mononucleosis-like syndrome, hepatitis, myocarditis, and hematologic abnormalities such as leukopenia, thrombocytopenia, hemophagocytic syndrome, and polyclonal or monoclonal lymphoproliferation, usually of B cells. EBV endomyocardial infection, as determined by detection of EBV viral genome in asymptomatic heart transplant recipients, has also been associated with premature graft loss as a result of premature development of advanced transplant coronary vasculopathy.¹³⁹

In young children, the transplanted organ is thought to be the most frequent source of EBV.³ Posttransplantation lymphoproliferative disorders (PTLDs) refer to B-cell expansion that may be localized, nodal, extranodal, or widely disseminated. The largest series of children who have undergone heart transplantation is from UPMC; in this series, PTLD developed in 7.7% (six of 78) of pediatric heart transplant recipients.²¹ A major risk factor for the subsequent development of PTLD was being seronegative for EBV before undergoing transplantation. PTLD developed in one-third of seronegative recipients of thoracic organs who acquired primary EBV infection (10 of 30). PTLD developed in none of the children who were seropositive before transplantation. Almost all these cases occurred within 1 year of transplantation.

In another series, 19 children were EBV-seropositive and 31 were EBV-seronegative before undergoing heart transplantation. PTLD developed in one of 19 patients who were seropositive before undergoing transplantation and in 12 of 19 who became seropositive after transplantation.²¹⁵ It did not develop in any of the 12 recipients who remained EBV-seronegative. In contrast to the UPMC experience, the mean time to confirmation of PTLD was 29 months (range, 3 to 72 months).

Webber and associates^{208,209} reviewed the experience with PTLD after heart transplantation among 1184 primary organ recipients in 19 centers from 1993 to 2002. Fifty-six patients (5%) developed PTLD a mean of 23.8 months posttransplantation. In a study from Germany, 12 of 147 (8.2%) developed PTLD a mean of 3.2 ± 2.2 years posttransplantation.¹⁷¹ Among 173 heart transplant recipients at the University of Toronto Hospital, 23 (13.3%) developed PTLD within a median of 4 years posttransplantation.¹²⁴ Higher maximum EBV viral load and longer duration of induction therapy were associated with increased risk of

PTLD. In a study among a multicenter group, PTLD developed in about 5% of 2374 children.⁶⁸ Pretransplant seropositivity for EBV and the receipt of induction treatment except OKT3 were associated with a reduced risk of developing PTLD. Chinnock et al. reported that, between 1993 and 2009, among 3170 pediatric heart transplant recipients at 35 institutions, 147 patients developed PTLD, with children age 1 to 10 years having the highest risk compared with children younger than 1 year or age 10 to 18 years.³¹ Similarly, data from the United Network for Organ Sharing (UNOS) database from 1987 to 2013 showed that 360 out of 6818 pediatric heart transplant recipients (5169 of whom had follow-up data on posttransplant malignancy) were diagnosed with PTLD and that PTLD was associated with reduced long-term survival after heart transplant.⁸⁶

Symptoms of PTLD may include fever, malaise, sore throat, and lymphadenopathy. Some children may have splenomegaly, CNS symptoms such as lethargy or seizures, or gastrointestinal complaints.^{17,21} Concurrent opportunistic infections are common. Nodules in the lung may be noted on chest radiographs (Fig. 70.1A).

The diagnosis of PTLD requires biopsy of involved tissue showing lymphoid proliferation with an immunoblastic component (Fig. 70.1B). Molecular techniques typically detect EBV nucleic acids in tissue (Fig. 70.1C). EBV serology is not particularly helpful after transplant but is important in the pretransplant evaluation to assess risk for posttransplant infection. Quantitative measurement of EBV DNA in peripheral blood is used to detect primary infection or reactivation at a very early time point and to monitor viral loads serially over time to detect PTLD in the timeliest manner.¹⁶¹ When reported as EBV copies per 10^5 peripheral blood lymphocytes, patients with PTLD typically have viral loads between 500 and 5000, which are much greater than the loads detected in normal latency.

Management generally involves decreasing the immunosuppressive regimen or discontinuing it temporarily. Anti-CD20 antibody (rituximab) is a monoclonal antibody that specifically binds to the CD20 antigen of normal and malignant B cells and results in antibody-dependent and complement-dependent cytotoxicity. Rituximab has been administered with success to children and adults with PTLD after they have undergone solid organ transplantation.^{54,171,175,126} Antiviral therapy with acyclovir or ganciclovir also is administered. Some centers administer ganciclovir, acyclovir, or intravenous γ -globulin for prevention of PTLD, although no prospective studies have confirmed that such an approach is efficacious.⁷⁹ Allen et al.³ have provided a detailed discussion of PTLD in solid organ transplant patients.

Toxoplasma gondii

An increased incidence of toxoplasmosis is apparent in recipients of heart transplants compared with other organ transplants, although it remains an uncommon infection after heart transplantation.¹⁸⁹ In the multiinstitutional study by the PHTS,¹⁶⁹ toxoplasmosis was not mentioned. *T. gondii* has a predilection for muscle and can be transmitted to the recipient from the heart of a seropositive donor. Active *T. gondii* infections may occur in donor hearts.¹⁶⁴ Less commonly, reactivation of old infection occurs in the recipient. The greatest risk for acquisition of toxoplasmosis occurs in a seronegative recipient of a heart from a seropositive donor. Clinical symptoms usually develop after the first postoperative month and generally within 3 months of transplantation.^{84,119,133} Fever alone may be the only clinical manifestation. Dissemination of the parasite to the CNS may lead to signs and symptoms of meningoencephalitis, such as lethargy, seizures, coma, and hemiparesis. Chorioretinitis may result in diminished visual acuity. A sepsis-like picture, pneumonia, and cutaneous lesions are unusual manifestations.¹⁰

CT or magnetic resonance imaging of the brain may detect ring-enhancing mass lesions, which typically are multiple and in periventricular locations. Definitive diagnosis of CNS toxoplasmosis requires the demonstration of tachyzoites or cysts in tissue on histopathology or by PCR. Serologic tests help monitor seronegative patients for seroconversion and allow a more aggressive approach to be taken with an early diagnosis of toxoplasmosis.¹⁸⁴ *T. gondii* has been seen on endomyocardial biopsy specimens routinely obtained to monitor for rejection.¹¹⁸

Therapy for toxoplasmosis with pyrimethamine and sulfadiazine may lead to recovery; these drugs also should be administered if the patient

FIG. 70.1 Eight-year-old boy with history of orthotopic heart transplantation secondary to restrictive cardiomyopathy. Donor was Epstein-Barr virus (EBV) positive and recipient was EBV negative. Six months after transplantation, the patient was diagnosed with EBV-positive monomorphic posttransplant lymphoproliferative disorder (PTLD)/diffuse large B-cell lymphoma. (A) PTLD/diffuse large B-cell lymphoma involving the lungs. Computed tomography scan showing innumerable pulmonary nodules. (B–C) PTLD/diffuse large B-cell lymphoma involving the colon (B, Hematoxylin and eosin, $\times 400$ magnification). Sheets of large, atypical B cells infiltrate the colonic mucosa (C, EBV-EBER in situ hybridization, $\times 400$ magnification). Large B cells demonstrate very strong nuclear positivity for EBV. (Courtesy Andrea N. Marcogliese, MD, Baylor College of Medicine and Texas Children's Hospital, Houston, TX.)

seroconverts.⁷⁰ Following treatment, life-long suppressive therapy with trimethoprim-sulfamethoxazole (TMP-SMX) is suggested.¹⁷³ Prophylactic (TMP-SMX) is recommended for seronegative recipients with seropositive donors.^{13,138,173} Some centers employ prophylactic administration of pyrimethamine to seronegative recipients of hearts from seropositive donors.²¹³ Spiramycin is not a useful prophylactic agent.¹⁸⁴

Aspergillus fumigatus

A. fumigatus is the non-*Candida* fungal infection most commonly reported outside the immediate postoperative period in most series and may be noted first at necropsy.¹⁴⁸ In a report from Stanford University Medical Center, 54 *Aspergillus* infections developed in 620 consecutive heart transplant recipients between 1980 and 1996.¹³⁸ Most commonly, *Aspergillus* infections were in the lung ($n = 31$) or were disseminated ($n = 17$). The median time to onset was 52 days. Disseminated aspergillosis was the most common infectious episode responsible for the highest mortality rates in this series. One child in UPMC series had disseminated aspergillosis.⁸⁰ Among 1854 children in the 2011 PHTS report, 18 had infection due to *Aspergillus* spp. (including nine pulmonary and five cutaneous infections), three due to Zygomycetes, and one due to *Exserohilum* spp.²¹⁶ Thirteen (59%) of the 22 patients with mold infection died. Risk was highest in the first 6 months after transplantation; prior surgery and the need for mechanical ventilation at transplant were independent risk factors for invasive fungal infection.

CNS invasion occurs in many patients with pulmonary aspergillosis, and aspergillosis is the most common cause of brain abscess in organ transplant recipients.^{84,137,183} Alterations in mental status occur most frequently, and seizures may occur in 40% of cases. Multifocal lesions are seen commonly on CT of the head and show a predilection for the junction of the gray and white matter. Mediastinitis and endocarditis are other manifestations of invasive aspergillosis.^{113,176} Although isolation of *Aspergillus* from respiratory secretions in a patient with pneumonitis does not establish a diagnosis, aspergillosis is so difficult to establish firmly and is so frequently fatal that treatment should be considered seriously based on this culture alone. Measurement of serum galactomannan levels may not be as helpful in recognizing this infection in heart transplant recipients as compared to oncology patients.¹⁴⁰ Measuring the galactomannan in the bronchoalveolar lavage fluid may more readily detect evidence of invasive pulmonary aspergillosis in solid organ transplant patients.³⁵

Voriconazole is the agent of choice for invasive aspergillosis.^{87,206} The reader is referred to the Chapter 198 on aspergillosis and the Infectious Diseases Society of America clinical guidelines for recommendations regarding therapy,²⁰⁶ as well as the review by Huprikar et al. on infections in solid organ transplant recipients due to less common and emerging fungi.⁹¹ Infection due to the endemic fungi following heart transplant also occurs depending on specific geographic regions. Unlike coccidioidomycosis, pretransplant serology for histoplasmosis is not recommended.¹³⁴

INFECTIONS AFTER THE SIXTH POSTOPERATIVE MONTH

Nocardia asteroides

A dry cough, fever, and the presence of a solitary pulmonary nodule or abscess on a chest radiograph are characteristic of infection with *N. asteroides*.^{109,182} Although pulmonary nodules are characteristic of *Nocardia*, *Aspergillus* and CMV can be associated with nodules as well.¹³⁸ Some patients are asymptomatic despite having an abnormal chest radiograph. Infection with *Nocardia* was noted in only 3% of cyclosporine-treated patients in the early Stanford University Medical Center series.⁸⁸ The median time to the onset of infection was 225 days. A similar incidence of lung nodules or masses secondary to *Nocardia* was noted in a series from New York.⁸⁵ In the follow-up Stanford series, 23 episodes of *Nocardia* infection (3.7%) occurred, with 19 in the lung.¹³⁸ The median onset of infection in the second series was 147 days. *Nocardia* infections are rare in pediatric heart transplant recipients.

Nocardia is isolated best from direct lung tissue specimens, but it also may be cultured from bone, skin, or other sites of involvement as well. If a cutaneous skin lesion of *Nocardia* is recognized, other sites should

be evaluated promptly for involvement.⁷⁴ The formation of single or multiple abscesses in the CNS may result from hematogenous dissemination. Seizures may develop after invasion of brain parenchyma.

For serious *N. asteroides* infection, initial treatment may be with a combination of imipenem or meropenem plus amikacin and/or (TMP-SMX) for 3 to 6 weeks followed by prolonged administration (6 to 12 months) of an oral agent.³⁶ The incidence of *Nocardia* infection has declined with the introduction of routine prophylaxis with (TMP-SMX).

Pneumocystis jirovecii

P. jirovecii (formerly *P. carinii*) pneumonia has been reported in 3% to 4% of heart transplantation recipients during the postcyclosporine era.^{62,81,88} In the early multiinstitutional study of the PHTS Group, *P. jirovecii* was noted in seven children (2.1%).¹⁶⁹ In the 2011 PHTS report, 18 of 1854 patients (1%) had *P. jirovecii* infection. Ninety-five percent of these infections occurred between 2 months and 2 years following transplantation.¹⁴¹ Fever, a nonproductive cough, and tachypnea are typical symptoms; hypoxemia is characteristic.²¹⁶ The chest radiograph classically shows a diffuse interstitial infiltrate that can progress rapidly. The most expeditious method of documenting *P. jirovecii* pneumonia in children is methenamine silver or specific antibody staining of fluid or tissue obtained by bronchoalveolar lavage or lung biopsy. Molecular diagnostics such as *P. jirovecii* quantitative PCR on bronchoalveolar lavage fluid are also being used more frequently, although differentiating between disease and colonization is not always straightforward.¹⁶⁸

Elevation in serum β -D-glucan concentration can be a clue to this infection. Coinfection with CMV or other pathogens occurs commonly.

Treatment of *Pneumocystis* pneumonia in a pediatric heart transplant recipient is identical to that for other immunocompromised children. Prophylaxis with (TMP-SMX) or some other agent is recommended for at least 6 to 12 months after transplantation.¹²⁷ Only one patient died in the PHTS study as a result of *Pneumocystis* pneumonia.¹⁴¹

Streptococcus pneumoniae

S. pneumoniae is an important community-acquired pathogen in heart transplant recipients who are at increased risk for acquiring this organism.⁴ In the multiinstitutional PHTS study, two episodes of pneumococcal infection were recorded.¹⁶⁹ During a 10-year period, nine (11%) of 80 cardiac transplant patients in Little Rock, Arkansas, had 12 episodes of pneumococcal bacteremia.¹⁹³ Over an 11-year period, four of 105 children undergoing heart transplantation in Toronto had systemic pneumococcal infections.¹⁹⁶ In the follow-up series from Stanford University Medical Center, seven pulmonary infections with *S. pneumoniae* were reported.¹³⁸ In an eight-center pediatric surveillance study spanning 5 years, pneumococcal infection developed in 10 patients after a median time from transplantation of 17 months (range, 5 to 76 months).¹⁷² Three of the 10 patients had two episodes, and one patient had three episodes of pneumococcal infection. The median age of the 10 patients at the time of the first pneumococcal infection was 26 months (range, 15 to 89 months). The pneumococcal serotypes of the isolates from these patients were the same as noted in healthy children. In a multicenter study, 15 children with invasive pneumococcal infections following solid organ transplantation were identified in eight pediatric centers from 2000 to 2014.¹⁴⁴ Most of the infections were bacteremia and/or pneumonia; nine isolates were not among the 13-valent pneumococcal conjugate vaccine serotypes.

Other Viruses

Influenza and parainfluenza viruses can cause serious infections at any time after transplantation, but especially in the immediate postoperative period.^{9,128} Additional risk factors for development of severe disease leading to death are young age and augmentation of immunosuppression. Fever, cough, rhinorrhea, and pharyngitis are typical symptoms of upper respiratory infections. More serious manifestations include acute respiratory distress syndrome; a requirement for intubation and mechanical ventilation; a sepsis-like picture; or CNS symptoms such as headache, photophobia, and lethargy. Bacterial or fungal superinfections are possible complications. Viral infection may enhance the likelihood of allograft rejection occurring.

For influenza A infection, oseltamivir should be considered in a child of any age and zanamivir for children 7 years of age or older with a heart transplant because of their enhanced predisposition for severe or complicated influenza infection.⁵ Recommendations vary depending on the susceptibility of the circulating influenza strains, and thus the treating physician needs to be aware of this information updated annually by the Centers for Disease Control and Prevention. Antiviral administration is recommended for more than 5 days in these patients who may have prolonged viral replication.¹²⁵ If intravenous administration is required, peramivir and a parenteral preparation of zanamivir are available on an investigational basis. Annual immunization with the inactivated influenza vaccine is recommended for heart transplant recipients and all family members. Additional information for respiratory viral infections in patients with solid organ transplants has been summarized by Manuel et al.¹²⁵

Parvovirus B19 infection is recognized to cause severe anemia associated with low or no reticulocytes as well as poor response to erythropoietin in recipients of heart transplants, similar to the red blood cell suppression in other immunosuppressed patients.¹⁴³ In one child, severe pneumonia developed in association with fever and a blanching maculopapular rash involving the face, trunk, and extremities.⁹³ The parvovirus B19 genome also has been detected in myocardial biopsy specimens of children experiencing cardiac allograft rejection. Of six children described in one report, one had a diffuse rash and two had persistent rejection despite receiving aggressive therapy.¹⁷⁰ In a series of children from Loma Linda University Medical Center who underwent myocardial biopsy for possible rejection, parvovirus genome was detected in five of 553 biopsy samples taken from 149 children.¹⁷⁷ The parvovirus B19 genome was the most commonly detected viral genome in endomyocardial biopsies from 99 children in one study.²⁴ The detection of parvovirus B19 genome did not correlate with cellular rejection, but if it was present chronically there was an association with transplant coronary artery disease. Intravenous immunoglobulin is beneficial for the treatment of anemia related to parvovirus B19, but its efficacy in treating pneumonia or possible allograft rejection is unknown.⁹⁵ The dose of intravenous immunoglobulin recommended is 400 mg/kg per day for 5 consecutive days.⁵³

Varicella virus infection remains a common childhood illness that can cause life-threatening disease in immunocompromised children.¹⁵⁰ In a group of 28 children younger than 10 years at the time of undergoing heart transplantation who had been monitored for at least 1 year between 1986 and 1999, 14 cases of primary infection with varicella zoster virus were identified.⁴⁶ The mean time posttransplant was 3 years (range, 9 months to 7.5 years). All children were seronegative at the time of transplantation. These children were treated successfully with either parenteral followed by oral acyclovir or oral valacyclovir (mean dose, 77 mg/kg per day) for 7 days. Only one child had recurrent varicella, and none had zoster. In a report of 314 adult heart transplant patients at Brigham and Women's Hospital, 51 patients had 60 episodes of herpes zoster, and cumulative zoster incidence was 0.078 at 1, 0.15 at 5, and 0.20 at 10 years.¹⁰⁴ Ideally pediatric heart transplant recipients should receive varicella vaccine prior to transplant if clinically feasible. Varicella vaccine is contraindicated after solid organ transplantation. Some patients do lose serologically measured immunity to varicella after undergoing transplantation, especially those children transplanted in the first 2 years of life.^{198,207} Routine administration of varicella vaccine to young children does help to decrease concerns about varicella developing after organ transplantation because of herd protection.

Adenovirus has been associated with serious infections after solid organ transplantation.^{64,65} Among 28 children with solid organ transplants (nine heart) and adenoviral infections, the most common symptoms were fever, diarrhea, vomiting, and abdominal pain.⁴⁰ Infection occurred a median of 1.6 months after transplantation. Only two of these patients received antiviral therapy, and all survived the infection. Cidofovir may be beneficial in some patients with disseminated infection, especially of the lungs, or with increasing viral loads determined by PCR.^{45,89} In asymptomatic heart transplant children, adenovirus genome detected in endomyocardial biopsies was associated with premature graft loss.¹³⁹

BK polyomavirus is associated with polyomavirus-associated nephropathy (PVAN) and kidney failure in kidney transplant recipients.

BOX 70.2 Effect of Various Antibiotics on Cyclosporine/Tacrolimus Levels

Increased Level

Clarithromycin
Azithromycin
Erythromycin
Ketoconazole
Fluconazole
Itraconazole
Posaconazole
Voriconazole
Caspofungin

Decreased Level

Sulfadiazine
Rifampin
Trimethoprim-sulfamethoxazole
? Nafcillin
? Isoniazid
? Ciprofloxacin (counteracts immunosuppression)

PVAN has been reported with increasing frequency in nonrenal solid organ transplant recipients as well, including adult and pediatric heart transplant patients.^{25,96,117,149} One systematic review identified the incidence of BK viruria and viremia in nonrenal solid organ transplant patients at 20% and 3%, respectively. Heart transplant recipients had a higher overall incidence of BK viremia than other nonrenal organ types, and the majority of cases of BK virus–associated nephropathy in nonrenal solid organ transplant recipients were in heart transplant patients.²⁰⁴ A single-center study of pediatric heart transplant patients found that, out of 98 heart transplant patients, 28 had BK viruria and seven had BK viremia. One viremic patient had biopsy-proven nephropathy that progressed to end-stage renal disease.⁴⁹

IMMUNOSUPPRESSIVE AGENTS AND ANTIBIOTICS

Cyclosporine and tacrolimus have improved the success of organ transplantation considerably. Generally the incidence of infection seems to be less since the introduction of cyclosporine than with the earlier immunosuppressive regimens, although morbidity rates remain high in heart transplant recipients. Cyclosporine and tacrolimus serum levels are monitored carefully to ensure that concentrations associated with optimal immunosuppression and minimal adverse effects are maintained. Some antibiotics interfere with the pharmacokinetics of cyclosporine or tacrolimus, which may lead to an increase or decrease in their levels.^{16,26,108,145,165,167,188,191,197} These interactions are outlined in Box 70.2. Because cyclosporine and tacrolimus are nephrotoxic, the antimicrobial agents (amphotericin B, aminoglycosides, acyclovir, cidofovir, foscarnet) administered to heart transplant recipients may be additive; renal function must be monitored carefully.

IMMUNIZATIONS

Guidelines for the immunization of patients after they have received a solid organ transplant have been published, although few studies examining the immunogenicity of selected vaccines in heart transplant recipients specifically have been conducted.^{39,126,163} Another prudent approach is to follow the recommendations that the Committee on Infectious Diseases of the American Academy of Pediatrics has developed for immunizing immunosuppressed children.⁷ Ideally the patient will have received the recommended routine vaccines before undergoing transplantation. For patients who do not receive recommended vaccines prior to transplant, most experts recommend waiting until approximately 6 months after transplant prior to administering immunizations. Influenza vaccine can be administered as early as 2 to 8 weeks after transplant, however, if there is an influenza outbreak at that time.

Children who have received transplants before reaching 2 to 3 years of age do not respond to the pneumococcal polysaccharide vaccine as well as do children who are older when they receive a transplanted heart, even though the vaccine is administered several years after they receive the transplant.⁷³ An impairment in immunoglobulin isotype switching from IgM to IgG and especially IgG2 seems to result from the immunosuppressive therapy that these children are receiving.⁷² In

one study, the antibody response of children aged 2 to 18 months following solid organ transplantation was compared with age-matched children to the 7-valent pneumococcal conjugate vaccine (PCV7) followed by the 23-valent polysaccharide vaccine (PV23) 2 months later.¹¹⁴ The antibody levels achieved were significantly higher in the controls, and a second dose of PCV7 given 2 months after the administration of the first PCV7 dose did not lead to higher antibody levels.

For previously unimmunized transplant recipients aged 2 to 18 years, the 13-valent pneumococcal conjugate vaccine is recommended, followed by the 23-valent pneumococcal vaccine at least 2 to 12 months later. Ideally children will have completed their PCV series before undergoing transplantation.⁶ Ongoing immunosuppression seems to prevent maturation of the response to polysaccharide antigens in younger children, which it is hoped that the conjugate vaccine can overcome. The 23-valent pneumococcal vaccine is less immunogenic in adults after they have undergone heart transplantation than it is in healthy controls.

Antibodies to the influenza vaccine develop in most children, but previous exposure predicts a better response.¹²⁹ Annual administration of influenza vaccine seems to be safe and immunogenic in children after they have undergone solid organ transplantation. In one study, low-level histologic rejection occurred after the administration of influenza vaccine.¹⁸ In a later study, the administration of inactivated influenza vaccine was not associated with an increased risk of rejection.²¹⁰ Depending on the time of year and the approximate date of transplantation, influenza vaccination is appropriate for the patient and all household contacts and health care workers to whom the patient might be exposed. The live-attenuated influenza vaccine is not recommended for individuals receiving immunosuppressive therapy or their close contacts.

After transplantation has been performed and after immunosuppressive therapy has been initiated, administration of live viral vaccines is contraindicated. The enhanced inactivated polio vaccine should be given to the child and to normal siblings. Measles, mumps, rubella, and varicella vaccines can be given to the siblings and adults in the household shown to have nonprotective antibody levels. Diphtheria, tetanus, and acellular pertussis inactivated vaccines should be given at the routine booster schedule, although antibody responses may not be equivalent to those observed in normal children. If varicella antibody is not detected at the pretransplant evaluation in a child aged 12 months or older, varicella vaccine should be administered at least 4 weeks before transplantation is performed if clinically feasible. Whether the antibody response data generated in children with leukemia during maintenance chemotherapy can be applied to heart transplant recipients who must continue daily immunosuppressive therapy is unclear.

Infections in Pediatric Lung Transplantation

71

Jill A. Hoffman

The first pediatric lung transplant was reported to the International Society for Heart and Lung Transplantation (ISHLT) in 1986 and, by June 2014, a total of 2090 pediatric lung transplants had been reported to the registry, with 124 reported in 2013.¹⁹⁶ Although there was a steady increase through the first decade of the 21st century in pediatric lung transplant procedures, these numbers have plateaued in the past 5 years.⁵⁷⁸ The reasons for this are likely multifactorial, but a primary one is the increased survival of persons with cystic fibrosis (CF), which is the leading indication for pediatric lung transplantation.^{4,176,542} Living lobar transplantation (LLT) has been performed at some centers as a way to address the shortage of available organs^{544,557,599,621}; the number of these procedures peaked in 1999 but almost all of the pediatric lung transplants in recent years have been performed with lobes from deceased donors. At Children's Hospital Los Angeles (CHLA), the first pediatric LLT was performed in 1993 on a 13-year-old boy with CF receiving lobes from each parent, and the last of 55 LLT procedures (49% of 113 total-lung and 12 heart-lung transplants) was performed at CHLA in 2004.³⁴⁷

The primary indication for lung transplantation in the pediatric population remains CF; from 2000 to 2014, 69% of the 726 11- to 17-year-olds in the ISHLT registry who underwent lung transplantation had CF, followed by 51% of 99 6- to 10-year-olds as well. Other indications, generally for younger children, include pulmonary arterial hypertension, congenital heart disease, surfactant protein B deficiency, and idiopathic pulmonary fibrosis. Infectious morbidity and mortality remain high for lung transplant recipients (LTRs).¹⁴ This incidence results from constant communication of the lungs and fresh bronchial anastomosis with the environment and from the high preoperative microbial burden of patients with CF. Denervation of the transplanted lung, interruption of the bronchial and lymphatic circulation, abnormal cough reflexes, and impaired mucociliary clearance also play roles.¹⁴ In addition, these patients receive high-dose, long-term immunosuppression; at 5 years, the majority of patients are still maintained on triple

immunosuppressant therapy including an antimetabolite such as mycophenolate mofetil (85%), a calcineurin inhibitor such as tacrolimus (98%), and corticosteroids (90%).^{196,578}

Predisposing factors for infection after lung transplantation derive from multiple sources: (1) the recipient, (2) the donor, (3) intraoperative factors, (4) posttransplant factors.²⁰⁶ An in-depth discussion of each of these issues is beyond the scope of this chapter, but rigorous screening algorithms are performed on donors and recipients using history, exposures, vaccination records, physical exam, and laboratory tests to identify infectious risks.¹⁶⁵ For any given solid organ transplant (SOT), the transplanted organ or organ space is the most common site of early postoperative infection, likely secondary to local immunologic and surgical factors; therefore, for LTRs, it is the lungs and the chest cavity. In addition underlying illness, such as CF, leading to organ dysfunction and, more importantly, microbial colonization and infection predispose LTRs to risk of infection. The microbiology of the CF lung has changed over the past decade, such that now *Staphylococcus aureus* (77%) (methicillin-susceptible [MSSA; 52%], and methicillin-resistant [MRSA; 26%]) is more prevalent than *Pseudomonas* spp. (50%) in CF sputum. In addition, the incidence of *Stenotrophomonas maltophilia* (14%) and *Achromobacter xylosoxidans* (6%) has increased.¹²² The age of the recipient affects risk of infection, with younger children more likely to have primary and more severe viral infections (herpes family virus, respiratory viruses) and immature immunologic responses and lack full vaccine protection at the time of transplantation. Donor-derived disease transmission can be expected (cytomegalovirus [CMV], Epstein-Barr virus [EBV]) and therefore monitored and/or treated to mitigate impact, or unexpected and lead to life-threatening infections in multiple organ recipients.²⁶⁴ Despite robust systems for donor risk assessment and testing (e.g., the US Organ Procurement and Transplantation Network), some donors may be asymptomatic or not tested for specific infections at the time of organ procurement. Infections with human immunodeficiency virus (HIV), hepatitis C, Chagas disease, rabies, lymphocytic

choriomeningitis virus, West Nile virus, and tuberculosis have all occurred in the transplant setting (see the later section “Donor-Derived and Zoonotic Infections”). In the first year after lung transplantation at CHLA, the overall incidence of infection was 0.24 episode per patient per month, or 2.88 infections per patient per year.³²⁷ Fifty-five percent of all infections occurred in the first month after transplantation, with infections becoming much less frequent thereafter (Table 71.1).³²⁷ A summary of the causes of infection in this cohort during the first year after transplantation is presented in Tables 71.2 and 71.3.³²⁷

The additional indirect impact of infections on the outcome of LTRs is also recognized. CMV and other viruses, as well as bacterial infections, have been implicated in immunologically mediated processes leading to bronchiolitis obliterans syndrome (BOS) or chronic graft dysfunction, acute rejection, graft loss, and death (see later discussion).^{14,196} The overall survival of pediatric LTRs (1990–2013; *n* = 1856) as reported to the ISHLT is 81%, 61.8%, 51%, 43%, and 36% at 1, 3, 5, 7 and 10 years, respectively. This survival is similar to that of adult recipients, with a transplant half-life (50% mortality rate in recipients) of 5.3 years.¹⁹⁶ There is no difference in survival according to donor lung source (i.e., living vs. deceased).^{45,557,599} Infection is the single most common cause of death from 1 month (16%) to 1 year (30%) after transplantation (2000–14), and it remains a significant cause of death in all periods through 5 years after transplantation.¹⁹⁶ In the series of 75 pediatric lung

transplants at CHLA (12 heart-lung, 18 cadaveric, 45 LLTs), the mortality rate was 18.6% at 1 year, with 50% attributed to infection.³²⁷

Death from graft failure has been reduced from causing a third of deaths in the first month to around 10% and up to a quarter of deaths thereafter.¹⁹⁶ BOS, progressive allograft dysfunction, causes 40% to 50% of deaths after the first year onward. The putative multifactorial mechanism of BOS is not completely elucidated but includes contributions from acute rejection episodes leading to chronic alloimmune injury, infections (especially viral CMV/respiratory and/or colonization with *Pseudomonas* or *Aspergillus*), and nonalloimmune factors such as primary graft dysfunction and gastroesophageal reflux.^{69,184,592,603}

IMMUNOSUPPRESSION AND TIMING OF INFECTION

An understanding of the mechanisms and effects of immunosuppressive therapy is fundamental to anticipating the timing and types of infections that occur after transplantation, and several excellent reviews on these subjects are available.^{110,483,489} The predictability of certain infections has facilitated establishing more timely diagnosis and determining strategies for preventive antimicrobial therapy.¹⁷⁰ A general timeline of the occurrence of specific infectious agents in pediatric lung transplant recipients is presented in Table 71.4.

OVERVIEW OF INFECTIONS AND ANTIBIOTIC USE IN SOLID-ORGAN TRANSPLANTATION

The “therapeutic prescription,” as described by Rubin and colleagues,⁴⁸⁹ for successful organ transplantation requires a careful balance between immunosuppression and the use of antimicrobial agents therapeutically, prophylactically, or preemptively to manage the risk for rejection versus infection. A transplant recipient’s risk for developing infection is determined by multiple factors including (1) the technical skill of the surgeon; (2) the quality of perioperative care; (3) the “net state of immunosuppression”; (4) the patient’s infectious exposure, including that from the community (past and present), hospital, and donor grafts; (5) the underlying condition of the patient (e.g., microbial colonization, organ dysfunction); and (6) the virulence of the organisms. Preventive/prophylactic strategies can alter these patterns, most notably for CMV and fungal infections, and delay their appearance past the expected time periods.⁴⁸⁷ In sum, these considerations indicate that although a standard set of antimicrobial agents can be prescribed, they must be tailored closely to the risks, exposure, and immunosuppression of each individual.⁴⁹⁰

General principles of infection and therapy have been proposed by Rubin and Marty⁴⁹⁰ and include the recognition that a transplant recipient is likely to have a greater microbial load and more advanced infection at the time of diagnosis, thus requiring longer therapy with greater potential for drug toxicity. Early establishment of the diagnosis and provision of therapy are paramount to a successful outcome. Furthermore a broader range of organisms must be considered. Although a common practice in medicine is to assume a single diagnosis for a given manifestation, a recognized caveat is that transplant recipients may have simultaneous and sequential infections. In fact, many infectious processes are influenced directly by proceeding or concurrent events. The prototype of this interaction is the immunomodulating effect of CMV infection such that alterations in the cytokine/chemokine milieu, T-lymphocyte subsets and function, neutrophil activity, and activation of endothelial cells emerge. The result of these derangements is further immunosuppression, enhanced production of virus, and subsequent increased susceptibility to additional infections. Other putative immunomodulating viruses include human herpesvirus–6 (HHV-6), EBV, and the hepatitis viruses.^{490,520} The effects of bacterial and fungal infections is not clearly understood but may also contribute to enhanced immunosuppression.

Length of therapy depends on consideration of the degree of current immunosuppression and location of the infection. In general, experts suggest that treatment be continued until all signs and symptoms of infection are gone, followed by a buffer period of weeks to months, depending on the infection.⁴⁹⁰ Finally drug interactions and toxicities, which may be synergistic, must be taken into consideration.^{366,489}

TABLE 71.1 Etiology of Infections in 75 Pediatric Lung Transplant Recipients in the First Postoperative Month at Children’s Hospital Los Angeles	
Etiology	No. of Episodes
<i>Pseudomonas</i> , respiratory tract	22
<i>Candida</i> , respiratory tract	13
Herpes stomatitis	12
Cytomegalovirus infection	10
<i>Aspergillus</i> infection of the respiratory tract, bronchial anastomosis	4

TABLE 71.2 Etiology of Infections in 75 Pediatric Lung Transplant Recipients in the First Year at Children’s Hospital Los Angeles	
Etiology	% of Total Infections
Bacterial infections	55
<i>Pseudomonas</i> spp.	18 (35% of bacterial infections)
Viral	27
Cytomegalovirus	12 (42% of viral infections)
Fungal	16
<i>Candida</i>	10
<i>Aspergillus</i>	4

9–12	7

TABLE 71.4 Timetable of Infections for Pediatric Lung Transplant Recipients

Time of Initial Evaluation	Infection/Pathogen	Comments
0–1 month	Wound, respiratory tract, line/bloodstream, and urinary tract infections HSV stomatitis CMV infection HHV-6? Bronchial anastomosis (<i>Aspergillus</i>) Other: rabies, West Nile virus, lymphocytic choriomeningitis virus, endemic mycoses	Related to the surgical procedure: <i>Candida</i> , <i>Staphylococcus</i> spp., <i>Pseudomonas</i> spp. Reactivation Unusual pathogens preexisting in the recipient or in the donor graft
1–6 months	CMV disease EBV <i>Aspergillus</i> <i>Mycobacterium tuberculosis</i> <i>Pneumocystis jiroveci</i> Endemic mycoses HHV-6 Respiratory tract, line/bloodstream, and urinary tract infections Respiratory viruses	Onset of opportunistic infections from immunosuppression Continued bacterial (<i>Pseudomonas</i>) and candidal infections common through 3–4 months Community-acquired infections
>6 months	Respiratory viruses Persistent <i>Pseudomonas</i> , <i>Burkholderia cepacia</i> , and <i>Aspergillus</i> infections Opportunistic infections: <i>Pneumocystis jiroveci</i> cryptococcosis, nontuberculous mycobacteria, EBV/PTLD, herpes zoster	Community-acquired infections Persistence of organisms from cystic fibrosis in the proximal airways and sinuses Patients receiving continuous high-level immunosuppression or therapy for steroid-resistant rejection, CMV infection

CMV, Cytomegalovirus; EBV, Epstein-Barr virus; HHV, human herpesvirus; HSV, herpes simplex virus; PTLD, posttransplant lymphoproliferative disease.

Modified from Rubin RH, Ikonen T, Gummert JF, Morris RE. The therapeutic prescription for the organ transplant recipient: the linkage of immunosuppression and antimicrobial strategies. *Transpl Infect Dis*. 1999;1:39.

SITES OF INFECTION

Thoracic Cavity: Respiratory Tract Infections, Including Pneumonia and Anastomotic Site Infections

The vast majority, up to 80%, of infections in LTRs occur in the thorax—lung, mediastinum, and pleural space, largely presenting as pneumonia.^{6,14,296,368} Prevalence rates of pulmonary infections as high as 60% in LTRs occur in the first month posttransplant. In the CHLA cohort of patients during the first 12 months after transplantation, 62% of all infections consisted of pneumonia.³²⁷ Organisms most frequently recovered include *Pseudomonas aeruginosa*, CMV, *Candida*, *Aspergillus*, and *S. aureus* (MRSA/MSSA) reflecting the high percentage of patients with CF in the transplant population.³⁵⁶ The common bacterial organisms are usually successfully treated without poor outcomes; the fungal infections, non-tuberculosis-mycobacteria (particularly *M. abscessus*), multidrug-resistant (MDR) gram-negative organisms, and *Burkholderia cepacia* complex (in many centers, *B. cenocepacia* is a contraindication for transplant) are often more challenging and life-threatening.³³⁸ The onset of pneumonia in LTRs appears in a bimodal pattern, with most cases occurring in the first few postoperative months. Surgical graft size reduction procedures to adjust for recipient/donor organ size mismatch and re-do transplantations are additional risks for early postoperative pneumonia.³⁶⁸ A second albeit smaller group has late (6 to 12 months) recurrent episodes of gram-negative pneumonia associated with a poor outcome. The immunologic consequences of these infections in some patients may include bronchiolitis obliterans with organizing pneumonia (BOOP), which is characterized by inflammation and fibrotic granulation tissue of the small airways extending into the alveoli. The mortality rate of patients with BOOP is high (50%), and those who survive appear to be at an increased risk for developing BOS (41%).^{14,99,203}

Unique to lung transplantation are bronchial anastomotic infections, most of which historically are fungal and caused by *Aspergillus* and *Candida*.^{217,234,298,420,434} The bronchial anastomosis is susceptible to such infections for a variety of reasons. Anatomically the posttransplant

bronchus is relatively devascularized, with the blood supply flowing retrograde from the pulmonary arterial circulation. Neovascularization from collateral vessels takes as long as 1 month to occur, and, in the interim, the bronchus may experience ischemia and subsequent necrosis and sloughing of bronchial epithelium. Evolving surgical techniques have diminished this risk for ischemia in recent years. This environment is optimal for developing infection caused by saprophytic flora, such as *Aspergillus*, present in ambient air to which the airways are in direct contact. In addition, local reaction to suture material, postoperative corticosteroid use, and immunosuppressive therapy have a negative impact on healing and increase the patient's susceptibility to infection. As a result of this early tenuous anatomy, infections at this site are most likely to occur within the first 2 to 3 months after surgery.^{104,217,234,421} Bronchial anastomotic infections rarely can lead to early catastrophic complications, such as dehiscence and hemorrhage. They are linked to substantial late bronchial complications, including dehiscence, bronchial stenosis, malacia, and retransplantation.^{408,420}

Although some studies have demonstrated that pretransplant isolation of *Aspergillus* spp. has not been found to be a risk factor for the development of *Aspergillus* infection after transplantation,^{421,439} others suggest that patients with CF and perioperative *Aspergillus* colonization may be at heightened risk for the development of early bronchial anastomotic infection. Postoperative isolation of *Aspergillus* from airways appears to identify patients at risk for the later development of bronchial anastomotic abnormalities.^{104,421} The overall incidence of airway infections and/or complications ranges from 5% to 25%.^{104,217,408,420} The mortality rate associated with bronchial anastomotic infection and its complications is reported to be 2% to 7%.^{234,420} Recent studies, including one pediatric series demonstrated airway complications of around 10%. Most were successfully treated conservatively without surgery and patient outcomes were not adversely affected.^{104,627} The current common practice of perioperative antifungal agents for patients with fungal colonization has likely decreased the rate of such infections. A 2010 ISHLT consensus statement formulated standardization of thoracic site infections in cardiothoracic transplant recipients, including pneumonia,

tracheobronchitis, bronchial anastomotic infections, and viral/CMV and fungal respiratory tract infections.²⁵⁵ The use of standard definitions going forward will better define the epidemiology of these infections and advance the quality of research aimed at therapeutic and prophylactic interventions.

Bloodstream Infections

The second most common site of infection is the bloodstream. Data are emerging regarding the epidemiology of bloodstream infections (BSI) in pediatric and adult LTRs.^{129,252,430} BSI occur in 12% to 26% of transplant recipients, with staphylococci, *Pseudomonas aeruginosa*, and *Candida* spp. being the most common organisms identified. Late infections consist of a wide range of gram-negative organisms. With increasing emphasis on reducing catheter-related BSI with infection prevention bundles for placement and maintenance of central line catheters, gram-positive BSI, especially coagulase-negative *Staphylococcus*, have decreased. Some SOT programs have reported gram-negative organisms with increasing numbers of MDR^{7,66,626} and resistant *Enterococcus faecium*, *S. aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Enterobacter* spp. (rESKAPE) organisms, whereas other studies demonstrate a predominance of gram-positive organisms, including in a large adult population, with a high rate of vancomycin-resistant enterococci.³² Posttransplant BSI, especially early (<30 days) infection in children and candidal infection in both adult and pediatric populations, was associated significantly with mortality. Infections are mostly related to pulmonary or vascular sites. In the pediatric population, most BSI were related to central venous catheters. These infections were most likely to occur in the first 7 days after transplantation. In adult transplant recipients, BSI largely were associated with pulmonary infections. Specifically *P. aeruginosa* bacteremia was more likely to develop in adult patients with CF (20% of the transplant cohort) than in patients with other indications for transplantation. In this study, BSI with *B. cepacia* and *S. aureus* were seen in similar frequency in non-CF patients, the former possibly related to a nosocomial outbreak.⁴³⁰ In children, *Pseudomonas* BSI was not associated with the diagnosis of CF (45% of the transplant cohort) nor with any outcome measures in this study. There exists an increasing concern for the impact of MDR organisms (MDRO), which were recovered in 57% of gram-negative-resistant bacteremias in one study (see later discussion).²⁵² In rare cases, MDRO BSI can be transmitted from donor allografts as well,³²³ with high rates of graft loss and mortality.

Empirical therapy in patients with suspected BSI should include agents active against staphylococcal and *Pseudomonas* spp. and be based on the patient's previous microbiologic susceptibilities and donor information, if available, with a low threshold for adding antifungal therapy. Furthermore the need for indwelling central catheters should be assessed routinely and catheters should be removed as soon as clinically feasible.

SELECTED PATHOGENS

Bacteria

Pseudomonas Aeruginosa and *Burkholderia Cepacia* Complex

P. aeruginosa and *B. cepacia* play prominent roles in postoperative infections in LTR with CF. Despite the removal of colonized lung tissue with the procedure, the proximal airways and sinuses remain colonized and a source of infection.³⁵¹ In patients with MDRO, this concern is heightened. Gram-negative MDRO have been defined as those resistant to one or more agents in three or more classes of effective drugs^{349,495,575} In addition, these bacteria exist in a biofilm in the airways of patients with CF, which greatly decreases therapeutic efficacy.^{117,535}

The presence of preoperative MDR *P. aeruginosa* may not have an impact on survival. Although these patients may be more likely to acquire postoperative infections, they generally respond to treatment without increases in short-term mortality rates. The most recent ISHLT guidelines for selection of LTRs list "colonization with highly resistant or highly virulent bacteria, fungi, or mycobacteria" as a relative contraindication.⁴²⁷ Additionally these guidelines acknowledge that although "certain resistant pathogens may increase risk for poor outcome ... it is not possible

currently to identify absolute contraindications based on either the type of organisms or the pattern of antibiotic resistance." Despite the status of the immunocompromised host, the relatively low virulence of some of these organisms, the new healthy lung epithelium and improved airway function of the transplanted lungs, the aggressive use of antimicrobial agents during and after the procedure, and discordance between in vitro susceptibilities and in vivo efficacy may account for the diminished influence that MDR pseudomonads have on the outcomes of transplant recipients.⁴²⁷

B. cepacia complex represents a group of nine related species that possess variable pathogenic potential in abnormal hosts.³³⁰ Misidentification of *B. cepacia* complex organisms at the genus (*Achromobacter/Alcaligenes*, *Stenotrophomonas*, and *Pseudomonas* most commonly) and species levels can occur.^{329,375} This information is critical to evaluating patients considering transplantation and, in postoperative care, to assessing their risk for developing invasive disease.³²⁹ In the United States there has been a decline in *B. cepacia* complex in the CF population, from 3.6% in 1995 to 2.5% in 2013.^{122,472} In Canada, this decline has also been documented from 15%, with as many as 80% of these involving *B. cenocepacia/genomovar III*,¹³⁹ to 4.6% in 2013 (40% *B. cenocepacia*, 30% *B. multivorans*).⁸⁹ This reassuring decrease in *B. cepacia* organisms is likely multifactorial, reflecting better microbiologic techniques for identification and infection control practices.⁴⁷² Controversy continues regarding performing transplantation on patients who harbor *B. cenocepacia*. Data demonstrate increased morbidity and mortality rates associated with this organism in nontransplanted patients with CF, including the occurrence of fatal cepacia syndrome.^{271,314,350} Multiple studies of LTR demonstrate an increase in mortality associated with pan-resistant *B. cenocepacia*, from 90% 1-year survival to 30%, and late deaths as a result of infection associated with BOS and possibly *Burkholderia gladiola* but not other *Burkholderia* spp. It remains a contraindication for transplantation in some centers,^{12,27,71,140,329,402,407} although successful transplantation has been accomplished with aggressive multidrug antimicrobial therapy, perhaps guided by multiple combination bactericidal testing, and a reduction in immunosuppressive therapy.^{139,327,407,575}

Optimal therapy for infections due to MDR *Pseudomonas* and *Burkholderia* spp. is not defined. Therapy should be tailored to susceptibility studies, with the recognition that in vitro susceptibilities may not correlate with in vivo activity and outcome.⁵³⁷ A biofilm-grown model of in vitro multiple combination bactericidal testing may better inform our therapeutic choices for these MDROs and has identified a combination of high-dose tobramycin (inhaled), plus meropenem and a third antimicrobial agent (piperacillin/tazobactam, trimethoprim/sulfamethoxazole [TMP-SMX], amikacin, or ceftazidime) that inhibited the growth of most isolates.¹²³ How these data translate to patient care, however, has yet to be fully demonstrated, and a recent Cochrane review found insufficient clinical evidence to recommend using biofilm susceptibility testing at this time.^{182,602} A study that compared CF patients receiving two-drug combinations based on multiple combination bactericidal testing versus clinician preference did not find differences in outcome measures,¹ but these patients did not necessarily have multidrug-resistant/pan-resistant organisms, nor had they failed conventional therapy. Extrapolating these results to LTR with MDROs is difficult. The CHLA transplant team used multiple combination bactericidal testing from the University of Ottawa between 2001 and 2009; our experience suggests that this approach, with three or four drugs used in combination, is helpful for managing preoperative and postoperative LTRs with multidrug-resistant/pan-resistant organisms, including *B. cepacia* complex.³²⁷ Clearly additional data are needed to assess this approach for LTRs infected with MDROs.

For LTR with susceptible *P. aeruginosa* infection, combination therapy is recommended, including an extended-spectrum, antipseudomonal β -lactam and an aminoglycoside, if renal status allows, at least for initial therapy (3 to 5 days) to limit nephrotoxicity. For MDR *Pseudomonas* spp., combinations of two and three drug classes, including antipseudomonal β -lactams + aminoglycosides \pm fluoroquinolones for 10 to 14 days is current expert recommendation.⁵⁷⁵ For resistant *B. cepacia* complex infections, combinations that include ceftazidime, meropenem, TMP-SMX, tetracyclines, quinolones, and

even chloramphenicol have been used.^{259,575} Aerosolized antibiotics (tobramycin, colistin, or aztreonam) can deliver drug levels above the minimal inhibitory concentrations of resistant organisms directly to the lungs and thereby reduce the bacterial burden with minimal systemic toxicity.^{190,371,384,422} As a rule, aerosolized antibiotics should not be used as single therapy for infection in LTRs because they are at risk for disseminated disease. A prophylactic protocol utilizing aerosolized aztreonam has been employed at CHLA.⁶²² Therapy is initiated in patients identified with *B. cepacia* complex, preoperatively if possible, and continued through the first year after transplantation. Data suggest that outcomes are similar to those of patients who are colonized with susceptible *Pseudomonas* organisms. Further investigation is needed in this promising area of therapy. Colistin aerosols may also be useful for the treatment of pan-resistant organisms.^{29,46} Although historically renal toxicity often precluded its systemic use, recent studies suggest that intravenous colistin can be used successfully as well.^{124,160} A recent publication described a series of pediatric patients who received IV colistin for MDR gram-negative infection (mostly CF patients with *Pseudomonas*⁵⁵⁸ spp.); 22% had renal injury, and resistance to colistin developed in 21%, possibly related to suboptimal dosing. All those with colistin resistant organisms died. Finally strategies that employ extended or continuous infusions of high-dose β -lactam antibiotics may optimize the pharmacokinetic/pharmacodynamic properties of these drugs and may improve outcome.^{397,477,575} The duration of therapy for these infections requires individualization but generally is not less than 2 weeks, and treatment should be continued for a significant period after the signs and symptoms of infection have resolved.

Multidrug-Drug Resistant Gram-Negative Organisms

A full discussion of extended spectrum β -lactamase (ESBL) and carbapenemase (CR) producing organisms is beyond the scope of this chapter. MDR ESBL-producing Enterobacteriaceae (*Klebsiella pneumoniae*, *Escherichia coli*) and *Acinetobacter baumannii* are being increasingly recognized as causes of infection worldwide. The extent of their impact on transplant recipients in general and in pediatric LTRs is unknown and limited to case reports and small surveys, mostly in adult transplant populations,^{28,53,443} and has been described in pediatric liver or intestinal transplantation, notably in outbreak situations.^{208,473} Given the rise in MDROs worldwide, it is expected that this problem is increasing in scope and imposing direct effects on morbidity and mortality on transplant recipients.^{94,323,575,600} Infections may originate from the recipient or donor.^{197,361} Increased risk related to antimicrobial exposure, infection control practices, invasive procedures, and prolonged hospitalization, especially associated with intensive care units, is likely. Carbapenems are considered the drugs of choice for ESBL-producing organisms, especially for empirical therapy,⁶¹⁷ although β -lactam/ β -lactam inhibitor combinations (such as piperacillin/tazobactam) may be appropriate based on in vitro susceptibilities, especially at high doses and depending on severity and site of infection.^{450,480,575} Carbapenem-resistant Enterobacteriaceae (CRE)-producing organisms provide additional challenges to therapy because the number of available effective agents is limited and few new options are in development. Several hospital outbreaks have demonstrated the lethality of these organisms in transplant recipients. In a series of adult solid organ transplant recipients (SOTR), infection with *K. pneumoniae* carbapenemase producers was associated with an overall 30-day mortality rate of 42%.⁵⁴ All of four adult LTRs died from CRE *A. baumannii* infections in one study; a 91% mortality rate⁴¹⁹ was demonstrated in 16 adult LTR with MDR *A. baumannii* infections⁵¹¹ in another. Optimal therapy is undefined; therapy should be guided by susceptibilities and possibly multiple combination bactericidal testing. Some data suggest that combination therapy may improve outcome, including the use of high-dose, prolonged infusions and dual carbapenem therapy,^{78,235,619} although sufficient prospective trials are lacking, especially in children. Other drug combinations including colistin, tigecycline, doripenem, aminoglycosides, and ceftobiprole may be considered.^{436,443,575} The transplant community continues to discuss the implications these organisms may have on transplant recipient and donor candidacy.⁵¹⁴ The basic tenet of infectious disease treatment remains important in these infections: that outcome depends not only on appropriate antimicrobials, but also on source

control, such as removal of infected foreign material and drainage of fluids.

Mycobacterium Tuberculosis

Worldwide *Mycobacterium tuberculosis* (MTB) remains an important pathogen in SOTRs, and the rate of infection is associated with the endemicity of infection. As noted by many authors, MTB behaves as an opportunistic infection in these patients in that its frequency in SOTRs is greatly increased in comparison with the normal population (up to 74-fold) and presents as diverse manifestations, including high rates of extrapulmonary disease and increased mortality rates.^{79,485,550} Most cases of infection with MTB in adult transplant recipients arise from reactivation of latent infection from recipient or donor; acquired cases are seen, especially in pediatric patients.^{79,373,396} Multiple cases of donor-derived MTB infection, including pulmonary MTB infection in LTRs⁴⁷⁶ and extrapulmonary MTB infection in renal and liver transplant patients, have been documented.^{205,476,618} In addition, nosocomial transmission to transplant recipients has occurred.²⁶⁹

Among SOTRs, MTB infections occur most frequently after lung transplants (1% to 6.5%).⁵⁶⁸ Studies of MTB infection in SOTR, including small numbers of children, suggest that most cases occur within the first posttransplant year, with a median time of 9 months for all SOTRs and 3.5 months for LTRs. Risk factors for MTB infection include allograft rejection; receipt of OKT3 or anti-T-cell antibodies, which also predict dissemination; previous exposure to MTB, with radiographic evidence of old infection or a history of a positive tuberculin skin test; renal failure/hemodialysis; liver disease; diabetes mellitus; and older age.^{79,568} Coinfection with CMV, mycoses, *Pneumocystis jiroveci*, and *Nocardia* has been associated with the development of disease.^{396,401} As would be expected, most manifestations include pulmonary disease (>70%), with interstitial infiltrates, nodules, effusion, and cavities seen on imaging studies.^{532,568} Presentations that include extrapulmonary disease, in up to one-third to one-half of active cases compared to 15% of normal hosts, involve the gastrointestinal tract, skin, musculoskeletal system, genitourinary system, lymph nodes, and central nervous system (CNS). Attributable mortality from MTB infection in SOTRs is reported to be 9.5% to 29%. Significant predictors of mortality are disseminated disease, previous rejection, and receipt of OKT3 or anti-T-cell antibodies.⁵³²

Several studies have investigated mycobacterial infections specifically in LTRs.^{73,281,353,396} Two of the studies were conducted in regions with a low endemicity of MTB infection—Australia and North America (affecting five to 15 per 100,000 population)—and two in Spain (25 to 49 per 100,000 population). Rates of MTB infection in LTRs in the two former studies were less than 1%, although still well above the national average,^{281,353} but they were 2.6% and 6.4% (500-fold higher than the national average) in the Spanish studies.^{73,396} Indeed nontuberculous mycobacterial infections were more common than were MTB infections in the first two reports, whereas nontuberculous mycobacterial infection was encountered only once in the Spanish study. Mortality rate ranged from 0% to 43%.^{73,281,396,532}

Few data exist on MTB infections in pediatric SOTRs, and none exist in LTRs. Although children have an age-related lower accumulated risk for being infected, even immunocompetent children with MTB infection are more likely to have progression to dissemination and mortality, especially those younger than 5 years of age and again during adolescence.¹¹⁹ This pattern appears to be mirrored in the transplant population. Small published series of MTB infection in SOTRs most often describe fever and pulmonary findings, with high rates of dissemination (50%); mortality ranged from 0% to 30%.^{79,373,580} Pediatric patients presented later after transplant than adults (median of 8 months vs. 4 months) as a result of differences in acquisition of disease. Tuberculin skin test results were negative or minimal in all patients. Furthermore screening of family members was very useful in both series of pediatric patients, thus suggesting that, as for immunocompetent children, the index case of exposure is in the home. Invasive diagnostic procedures were needed to confirm the diagnosis in many patients. A screening risk assessment with history, including exposures, travel, receipt of bacille Calmette-Guérin (BCG) vaccine, and physical examination, as well as performing a tuberculin skin test should be documented in all pediatric transplant candidates.^{79,550} A 5-mm induration should be considered

positive in an immunocompromised child because positive results require intact T-cell function; false-negative results may be secondary to nutritional status, organ failure, or medication-related immunodeficient states.^{16,79} Screening of household contacts should also be considered. Interferon- γ (IFN- γ) release assays (IGRA) have emerged as valuable tools for the screening/diagnosis of latent tuberculosis infection. The T-SPOT.TB test may be more sensitive in immunocompromised patients.^{369,464,474} However, the use of IGRA in young children (<5 years) and immunocompromised patients is still being evaluated and may not perform optimally in children with T-cell immunodepression, although controls are contained in the testing procedure.^{345,369,464,474,561} Both the tuberculin skin test and the IGRAs, along with clinical, radiologic, and microbiologic investigations, should be used to increase the sensitivity of diagnosis because discordant results in children and immunocompromised populations have been well documented.^{3,79,306}

Diagnosis of active MTB infection in the transplant setting can be challenging because symptoms may be nonspecific, such as fever of unknown origin, or unusual, such as abdominal manifestations; coinfections may also modify the signs and symptoms, and immune response-based diagnostic methods lack sensitivity. Consequently a high index of suspicion is required, and, frequently, aggressive diagnostic techniques, such as bronchoscopy, laparoscopy, and tissue biopsy, are needed.³⁷³ The American Thoracic Society and the Centers for Disease Control and Prevention (CDC) have published recommendations for diagnosis of MTB disease.^{23,92,503} Several methods are available for culture-based diagnosis. Broth-based culture systems coupled with DNA probes allow more rapid establishment of a diagnosis.⁵⁰³ Technologies for the rapid detection of MDROs are evolving.^{30,91,96,395,503,559} Because pediatric LTRs are at heightened risk for development of progressive tuberculous infection, expert opinion supports the use of 9 months of isoniazid (INH) chemoprophylaxis for pediatric candidates or recipients with latent tuberculosis. The morbidity and mortality from MTB is high enough to warrant the risk for potential hepatotoxicity in most cases unless severe liver disease is also present.^{79,401,550} Rifampin alone may also be an acceptable regimen, although drug-drug interactions are common (see later discussion). Completing therapy prior to transplant is optimal, but it can be accomplished after transplantation. An alternative strategy is active surveillance, with initiation of INH only if additional risk factors are present, such as recent conversion, exposure to active MTB, a recipient or donor with a history of MTB infection without adequate therapy, or the existence of significant abnormalities on chest radiographs.⁴⁸⁵ All family and close contacts with latent or active tuberculosis should also be treated.⁷⁹

Optimal therapy for pediatric LTR with active tuberculosis has not been defined, but an empirical multidrug regimen such as those recommended for active disease in other populations, modified by susceptibilities or known resistance patterns as necessary, should be initiated.^{19,65,405,550} Complicating factors include liver toxicity and drug interactions. INH, especially in combination with other first-line drugs, such as rifampin and pyrazinamide, can lead to toxicity, requiring discontinuation of all or some of these drugs and the need to institute new regimens.^{401,532} Liver biopsy may be necessary to distinguish drug toxicity from rejection (in liver transplantation) or hepatic granuloma from MTB infection.^{401,485,532} Pediatric patients generally tolerate first-line therapy, with occasional need for reduced dosage and rarely discontinuation.^{19,65} For patients with suspected or proved MDR tuberculosis, close consultation with public health services and specialists in treating this disease should be employed for optimal management.

The use of rifampin in SOTRs deserves special comment. Although rifampin-containing regimens may portend the best microbiologic outcome, significant morbidity from graft dysfunction and loss can be due to the simultaneous use of rifampin with immunosuppressant agents. Rifampin considerably lowers serum levels of cyclosporine, tacrolimus, and azole antifungals, especially fluconazole, as well as causing some decrease in corticosteroid levels via induction of cytochrome P-450.¹⁴⁹ Current recommendations suggest that rifampin can be used successfully with increased calcineurin inhibitor dosing and careful monitoring of calcineurin inhibitor serum levels.³⁵³ Rifabutin may offer equivalent efficacy with less effect on drug interactions, as has been documented in tuberculosis/HIV coinfecting individuals on antiretroviral

therapy.⁷⁹ Others suggest that a longer duration of therapy (up to 50%) with rifampin-free/INH-containing regimens has a comparable outcome without the risk for rejection and potential graft loss.^{73,401} Most authors agree that regimens should contain INH if at all possible.^{73,79,401,550} If rifampin-free regimens are used, therapy should be prolonged to a minimum of 12 to 18 months.⁷³ Ethambutol and second-line therapies (aminoglycosides and quinolones) may be considered if a first-line drug cannot be used.^{401,485} If both INH and rifampin are not used because of toxicity, drug interactions, or resistance, therapy should be continued for a prolonged period, possibly 2 to 3 years.^{79,485} Patients should be monitored very closely for response to therapy, adherence to medications, drug interactions, and adverse reactions throughout the entire treatment period.³⁰⁶

Nontuberculous Mycobacterial Infections

Nontuberculous mycobacterial (NTM) infections are more common in LTRs than are MTB infections in those areas where MTB is not endemic, including the United States.^{152,213} Patients with chronic lung disease and CF in particular have a high incidence of NTM colonization. More recent data suggest that 6% to 24% of patients with CF are colonized with NTM organisms, most commonly *M. abscessus* (subsp *abscessus*, *bolletii*, *massiliense*) or *M. avium* complex (MAC).^{89,98,122,331,467} The contribution of these organisms to progression of lung disease in pretransplant patients is still being defined.⁴²⁶ The impact of NTM infections on the LTR, especially from infections due to *M. abscessus*, deserves emphasis. Although there remain many gaps in knowledge regarding the epidemiology and best approaches pre- and postoperatively to patients with NTM infections, it appears to be increasingly reported in lung transplant populations and is quite therapeutically challenging.

Clinical manifestations of NTM infection in lung transplantation vary by organism and include pulmonary, surgical site infections, and cutaneous and disseminated disease.¹⁵² In a survey of 31 transplant centers regarding *M. abscessus* infection in LTRs, 17 patients were identified (0.33%).¹⁰² The majority had pulmonary infections, followed by skin involvement; several patients had both. Disease occurred at a median of 18.5 months after transplantation (1 to 111 months). Pulmonary disease may manifest as chronic cough, sputum production, weight loss, and fatigue. Skin infections may involve surgical sites (sternal wounds) and extremities.^{98,353} Painful, erythematous cutaneous or subcutaneous nodules may develop into abscesses and ulcerate.¹⁰² In additional single-center retrospective studies involving adult LTRs, most of whom underwent transplants because of chronic obstructive pulmonary disease (COPD), the rate of posttransplant NTM infection was 4% to 22%,^{205,244,353} with progression to disease in 25% with pulmonary infection and 11% with pulmonary and surgical site infections of those colonized.²⁴⁴ A study of end-stage CF patients referred for transplantation revealed 20% of patients were colonized with NTM organisms (equal numbers of MAC and *M. abscessus*); after the transplant, NTM were isolated from 14% of CF LTRs. The prevalence of posttransplant invasive disease was approximately 3% (25% of those colonized) in both pulmonary and surgical site infections, the majority being caused by *M. abscessus*.⁹⁸ Posttransplant NTM infection, disease, and even colonization has been associated with increased risk of mortality posttransplantation.²⁴⁴ The presence of NTM is suggested as a marker of “overimmunosuppression”; in support of this is the higher mortality rate attributable to non-NTM infections as well, seen in LTRs with NTM. Emerging data support the association between preoperative colonization and post-transplant infections with *M. abscessus*, and, although LTRs may remain asymptotically colonized, serious and sometimes fatal posttransplant infections are documented.^{98,102,152,629}

Transmission from water and environmental sources is most common, including hospital and household plumbing systems, and health care-associated outbreaks related to laparoscopic surgery, cosmetic procedures, and surgical tourism are increasingly noted.⁵³⁶ In addition, recent investigation using whole-genome sequencing, diversity analysis, resistance patterns, and epidemiologic data suggests there is evidence of person-to-person transmission of *M. abscessus* subsp. *massiliense*, albeit indirectly by way of fomites. The exact mechanism has yet to be defined, but additional data support that transmission can occur from persons with negative smears/positive cultures, suggesting that a low

quantity of inoculum is required. To further define the existence of transmissible⁷⁷ *M. abscessus* clones despite current infection prevention measures will require new paradigms to protect patients from these infections.

Diagnosis requires a high level of suspicion. Cutaneous lesions should be sampled for histology, special stains, and culture. The infectious differential diagnosis includes fungal, nocardial, and other atypical infections. These organisms are ubiquitous, and differentiating respiratory tract colonization from infection may be difficult. The diagnosis of NTM infection should be entertained with a low threshold for performing bronchoalveolar lavage (BAL) or biopsy, for any unexplained or unresolving pleuropulmonary disease.^{152,213} The American Thoracic Society/ Infectious Diseases Society of America (ATS/IDSA) has published diagnostic criteria that include signs and symptoms present after the treatment of other possible causes of findings, such as radiologic evidence of progressive pulmonary disease, including infiltrates, cavities, nodules, or bronchiectasis, and bacteriologic evidence of NTM infection, generally on at least two respiratory or biopsy specimens.²¹²

Providing therapy for NTM infection may be challenging, depends on the species isolated, and should be determined in consultation with experts and adherence to the ATS/IDSA guidelines.²¹³ Despite the use of seemingly adequate therapy, failures and recurrences are common.^{212,213} Therapy for infection with MAC includes a macrolide, ethambutol, and rifampin, with or without an aminoglycoside, depending on the severity of disease. Susceptibility to macrolides should be performed; it is the only class of drug for MAC for which there is evidence to support an in vitro and in vivo response.²¹³ The optimal therapy for *M. abscessus* infection is undefined because this organism is notoriously resistant to many antimicrobial agents, and success is not always achieved using in vitro susceptibility profiles. See Chapter 97 for details of treating atypical mycobacterial infections. For SOT patients, reduction of immunosuppression, surgical excision or debridement, and treatment of coinfections, in conjunction with long-term therapy with multiple antimicrobial agents, likely improve the outcome.¹⁰² Relapses are not uncommon. Consideration of lifelong suppression is recommended by some experts for patients with a high burden of disease and persistently high levels of immunosuppression.^{244,536} Most patients (~70%) who can complete long-term therapy improve and half of these are considered cured; minimal response to therapy was seen in about a quarter of LTRs. Fatal infections occur rarely.^{102,289,498} Drug interactions between macrolides and rifampin and between calcineurin inhibitors and sirolimus occur. Both can lower serum levels of immunosuppressive drugs and trigger rejection.

Most centers do not currently consider the presence of NTM infection an exclusion to transplantation, although the optimal management of these patients is debated. Clearly patients often remain colonized in respiratory tree sites above the anastomosis. Given the concern for emergence of resistance, toxicity and drug-drug interactions related to long-term therapy, prolonged antimycobacterial therapy cannot be recommended for all patients. Some centers opt for pretransplant or peritransplant prophylaxis, whereas others recommend observation for evidence of disease.¹⁵²

Fungal Infections

Aspergillus

Aspergillus infections remain a major challenge to the success of lung transplantation. Most common presentations involve the respiratory tree (up to 90%), with manifestations ranging from semiinvasive tracheobronchitis and bronchial anastomotic infections to invasive pulmonary disease and, rarely, dissemination to extrapulmonary sites, including the CNS (10%).^{187,525} The published rates of invasive aspergillosis (IA) infections vary considerably (4% to 35%) and probably reflect differences in dates of publication, patient populations, underlying disease such as CF, net state of immunosuppression, use of prophylactic measures, local issues of exposure (e.g., construction), and rates of rejection and viral infection, among others.^{189,411,526} In addition, distinguishing between colonization of the airway by *Aspergillus* versus true invasive disease may be difficult. Despite these caveats, rates of IA infection in LTRs are the highest among SOTRs. Studies suggest that invasive disease occurs in 3% to 33% of LTRs, although rates of

colonization/isolation of *Aspergillus* may be considerably higher. In most cases, colonization appears to be transient and does not lead to invasive disease.*

A bimodal pattern of the development of IA in transplant recipients has been recognized. Most infections develop 1 to 6 months after transplantation and are a major cause of death during this time period.^{130,298,377,389,410,525} but late infections after 1 year posttransplant occur as well.^{187,335,410} Infections that develop less than 3 months after transplantation are more likely to be tracheobronchitis or bronchial anastomosis site infections; patients who require retransplantation or have bronchial anastomotic infection may present in the first month.^{104,217,234,389} Invasive pulmonary or disseminated aspergillosis may occur at any time.^{130,335,410,525,539} Risk factors for early disease in LTRs include *Aspergillus* colonization in the 6 months before transplantation or early posttransplant colonization, a complicated postoperative period, A2 or repeated rejection, and CMV disease or receipt of CMV prophylaxis as a marker for donor/recipient seropositivity. In a study of adult CF LTRs, a positive intraoperative BAL *Aspergillus* culture from the native lung produced a fourfold higher risk of developing IA³⁴⁰ compared to positive pretransplant cultures.^{130,187,232,263,335,393,421} Corroboration of the importance of CMV is the observation that a significant decrease in IA was associated with the use of prophylactic ganciclovir in heart transplant recipients, reflecting the immunomodulating effects of the virus on host immune status.^{486,595} Adult patients in whom IA developed later after transplantation were older and “over immunosuppressed” secondary to chronic or refractory graft rejection or dysfunction.^{187,528} In both the early and late groups, IA was associated with renal failure and repeated bacterial infections.

A. fumigatus causes the majority of disease, although non-*A. fumigatus* species are becoming more common.³⁷⁷ Such species include *A. flavus*, *A. niger*, *A. nodularis*, *A. ustus*, and *A. terreus*. Clinical findings in patients with pulmonary disease are largely nonspecific and may include cough, shortness of breath, and hypoxia, although chest pain and occasionally hemoptysis may raise clinical suspicion of infection with IA.⁴⁴ Symptoms are seen more commonly in patients with diffuse disease than in those with focal or nodular disease. Although fever is a common early manifestation of infection with IA in neutropenic patients with a hematologic disorder, it occurred in only 15% of LTRs with IA and usually more often in patients with disseminated (50%) or invasive pulmonary disease (20%) than in those with tracheobronchial or bronchial anastomotic infections (0%).⁵²⁵ Lack of fever also has been documented in other studies of nonneutropenic patients with IA. Patients with disseminated disease may have involvement of the sinuses, orbits, musculoskeletal system (osteomyelitis), ophthalmologic structures, cutaneous sites, and CNS. Symptoms of CNS disease may include headache, sinus pain, cranial nerve abnormalities, seizures, changes in mental status, or other focal neurologic findings.^{44,200}

The radiologic manifestations of IA in LTRs are highly variable.^{147,512,564} Chest radiographs are insensitive and nonspecific. Computed tomography (CT) of the chest has become an integral part of early diagnostic strategies and has been incorporated into recent definitions of invasive fungal infections in immunocompromised hosts.¹³⁷ On chest CT scans of neutropenic adults, large nodules and cavitary lesions are common findings.^{84,137} In addition, much has been made of the early halo sign, a macronodule surrounded by a perimeter of ground-glass opacity (edema and hemorrhage), and the later air crescent sign, a crescent-shaped air interface between viable lung and infarcted tissue at the periphery of a nodule that is seen with recovery and return of neutrophils. These findings are considered highly suggestive, although not pathognomonic, of IA. Unfortunately these findings are seen less commonly in LTRs and in children in general. Multiple ill-defined pulmonary nodules were the most common findings in adult LTR, with approximately half demonstrating halo signs. Cavitation was rarely seen, and no air crescent signs were observed.¹⁴⁷ In children, radiographic findings were highly variable and included consolidations and small nodular masses and effusions, with little evidence of cavitation or halo or crescent signs.^{80,564}

The gold standard for diagnosis of IA is the demonstration of small hyaline, septate, dichotomously branched hyphae in tissue with evidence

*References 130, 187, 200, 232, 335, 377, 389, 393, 410, 421, 437, 525.

of associated tissue damage or positive cultures from a normally sterile body site in the presence of signs and symptoms of invasive disease.^{137,240} Blood cultures are rarely positive. Obtaining adequate tissue specimens in a timely manner frequently is not possible. An immunocompromised patient with neutropenia or one who is on corticosteroid therapy may not exhibit obvious signs or symptoms of invasive disease until late in the course of infection.¹⁰ Additionally these patients are often deemed too ill to undergo the invasive procedures necessary to obtain tissue for microbiologic and histopathologic evaluation.⁵³³ Therefore the diagnosis is established late in the course of the disease or at autopsy. Indeed, frequently it is not established but is based on radiologic and host factors.

Early diagnosis is thought to be critical to improving the outcome of patients with IA, especially now with the availability of more active therapeutic agents. In addition to early CT in high-risk patients, especially those who do not respond to broad-spectrum antibacterial therapy, there have been several recent advances in molecular/non-culture-based approaches to establishing a diagnosis. The most widely used and well characterized of these modalities is the Platelia *Aspergillus* serum galactomannan antigen, detected by double-sandwich enzyme-linked immunosorbent assay (ELISA).^{95,348,380,608} In SOTRs and nonneutropenic patients, galactomannan antigen testing of blood appears to be less sensitive (30% compared to 80% to 90%) for the detection of IA.^{174,254,305,458,583} In addition, antifungal therapy has been shown to decrease the sensitivity of the assay.³⁵⁸ However its use in BAL fluid may have a higher diagnostic yield and has been recently approved by the U.S. Food and Drug Administration (FDA) for this use.^{50,141,288} Several studies in LTRs suggest that galactomannan antigen levels greater than 1.0 from BAL fluid evaluation have good sensitivity (60–100%) and specificity (90–98%) for determination of IA.^{220,253,257,442,526} Galactomannan antigen values between 0.5 and 1.0 should be interpreted in clinical context.

The Fungitell (1→3)- β -D-glucan assay measures a cell wall component found in many fungi, including *Aspergillus* and *Candida* spp. and *Pneumocystis*, but, like galactomannan antigen, it does not detect *Zygomycetes*.⁴²⁸ It is approved by the FDA to aid in the diagnosis of invasive fungal infections and has been incorporated into the definitions for these infections.¹³⁷ Cross-reacting glucan-containing material occurs commonly in the environment, and false-positive tests have been demonstrated in dialysis patients, those exposed to gauze, and those with some gram-positive bacteremia. In addition, false-positive results are associated with the use of some antimicrobial agents and with sample manipulation, thus suggesting that laboratory contamination is possible.^{240,364,608} A study in LTRs suggests it has a low positive predictive value, thus limiting its use as a screening tool, and false-positive findings occurred with mold colonization and hemodialysis. Unlike serum galactomannan antigen, it does not appear to correlate with response to therapy or have prognostic value because it declines slowly, even with clinical improvement.^{13,292} Most recently a point of care test for an *Aspergillus*-specific later flow device (LPD) is being developed.^{237,270,381,615} This diagnostic modality detects *Aspergillus* extracellular glycoprotein antigen by monoclonal antibody JF5 on BAL fluid. Results are available in 15 minutes. The LPD has a negative predictive value of 95% to 97%, sensitivity of 64% to 100% (depending on the patient population), and a specificity of 83% to 94%. This test may be most helpful for ruling out IA, but further study is needed to determine its application in different patient populations.

Despite historically poor outcomes of IA in immunocompromised patients, new mold-active therapies appear to be associated with improving mortality figures.⁴¹⁸ The IDSA practice guidelines for *Aspergillus* infections published in 2016 recommends therapy with voriconazole as primary therapy for most patients⁴⁴⁶ because it has demonstrated outcome superiority, even for CNS infection.^{40,137,505,598} Data now support the use of voriconazole for IA in pediatric patients and SOTRs. ISHLT published guidelines for management of fungal infections in cardiothoracic SOTRs in 2015, giving recommendations for prophylaxis, diagnosis, and treatment as well, which corroborate those of IDSA but are transplant-specific.²⁶⁰ Pediatric patients require higher doses on per kilogram basis (generally 7 to 10 mg/kg per dose twice a day).^{58,76,392,409,441,446,540} In addition the importance of therapeutic drug

monitoring (TDM) of voriconazole as it relates to improved outcome and decreased toxicity, with trough levels between 1 and 5 μ g/mL especially in children and other patient populations, including those with CF, has been demonstrated.⁴ Several important drug interactions occur with medications routinely used in SOTRs. The most important of these interactions involves tacrolimus and sirolimus, in which concomitant use with voriconazole can lead to decreased metabolism via cytochrome P-450 and result in greatly increased serum levels of the immunosuppressant.⁴⁹² The use of tacrolimus can be controlled safely by reducing the dose by 50% and monitoring daily levels.^{492,581} The effect of voriconazole on sirolimus levels is even more pronounced, and it is labeled as an absolute contraindication by the manufacturer.^{492,493} Several case reports and small series describe the use of these two drugs together, with significant dose reduction of sirolimus (up to 90%) and close follow-up of serum sirolimus levels.^{363,367,493} The use of rifampin and voriconazole should be avoided if possible because voriconazole levels may be significantly decreased in this setting.¹⁸⁸ Posaconazole, a broad-spectrum azole with activity against many non-*Aspergillus* molds and *Zygomycetes* is recommended as an alternative for treatment of IA infection in patients refractory or intolerant of other therapy, including voriconazole.^{11,297,446,507} It is also licensed for prophylaxis in patients 13 years of age and older with fever and neutropenia or graft-versus-host disease.^{114,572} Its safety and drug interaction profile is similar, if not improved, compared to that of voriconazole, and TDM is also recommended.⁵¹⁰ On the other hand, optimal dosing remains an issue, especially in young children for whom no specific dose recommendations exist.⁶⁰⁵ A new delayed-release pill formulation with improved bioavailability makes this antifungal an option for patients who can swallow pills, especially if toxicity (hepatic, dermatologic, neurologic) or achieving adequate levels limit voriconazole's use.^{113,121} See Chapter 198 for complete information regarding treatment of IA.

The role of combination therapy in the treatment of IA remains undefined.^{527,563,616} A survey of IA in transplant recipients documented that primary combination therapy was used in 35% of patients.³⁷ A study comparing voriconazole/caspofungin as primary therapy in SOT with IA (proven/probable) in a prospective multicenter study (2003 to 2005) with historical controls who had received a lipid formulation of amphotericin B (LFAB; 1999 to 2002).⁵²⁷ There was a trend toward improved survival in the combination cohort and an improved 90-day survival in patients receiving combination therapy with renal failure and those with *A. fumigatus* infections. Only one only randomized, double-blind, placebo-controlled trial to date has compared voriconazole and voriconazole/anidulafungin as primary therapy for IA in adults with hematologic malignancies and stem cell transplant.³⁵⁹ Unfortunately the study had limitations that reduced its power to detect treatment effect and generalizability. The results demonstrated “combination therapy was associated with a substantial, but not statistically significant reduction in overall mortality.” In post hoc analysis of a dominant subgroup of patients with IA based on CT findings and galactomannan positivity, all-cause mortality at 6 weeks was improved in those patients who received combination versus monotherapy. Although these studies are not definitive, not generalizable to all patient populations, and do not include children, they do provide additional support for primary combination therapy for IA in some patients. The most recent IDSA guidelines (2016) on the treatment of IA state that “combination therapy ... has been supported by generally favorable in vitro and in vivo preclinical data. ... Non-randomized clinical trial data suggest the benefit” as do limited prospective randomized first-line combination therapy. For these reasons, current guidelines suggest “consideration for an echinocandin with voriconazole for primary therapy in the setting of severe disease, especially in patients with hematologic malignancy and those with profound and persistent neutropenia.”⁴⁴⁶

No definitive data are available on the length of treatment for IA, although the natural history of disease, assessment of risk factors, and the state and length of immunosuppression, along with investigations on response to therapy and animal studies, inform us on regimens most likely to be effective. Clearly one must balance the risk for incomplete therapy and recurrent disease with the dangers of increased toxicity

*References 55, 58, 76, 150, 233, 273, 284, 341, 392, 409, 440, 540.

and expense from prolonged therapy. One thoughtful approach based on these many variables suggests use of the “most effective therapy first for 10 to 12 weeks, or for at least 4 to 6 weeks beyond resolution of all clinical and radiographic abnormalities, whichever is longer.”⁵¹⁹ Length of therapy should be individualized, and factors such as recovery from neutropenia or other immunocompromised state, net state of immunosuppression, extent of disease, presence of graft-versus-host disease, and coinfections (e.g., with CMV) predict poorer outcome and slower response and probably will prolong duration of therapy for patients with these comorbid findings.

Adjunctive surgical therapy may be recommended for cutaneous and soft tissue infections²³⁰ or for lesions on the great vessels or major airways to prevent massive hemoptysis.^{56,83,85,429} Immunomodulatory strategies to improve host immune response, in theory, are attractive adjuvant therapies. Alveolar macrophages, polymorphonuclear neutrophils, and pulmonary dendritic cells are critical first-line defenses against IA.⁴⁸¹ Decreasing the use of immunosuppression and corticosteroids as much as possible should be the goal in transplant recipients with IA. Additional strategies, including enhancement of T-helper type 1 (T_H1) immune responses, exogenous administration of colony-stimulating factors (granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage colony-stimulating factor [GM-CSF]) or cytokines (IFN- γ) to activate or recruit phagocytes (or both), and G-CSF donor-primed white blood cell transfusions have been investigated and may be used in select cases.^{446,545} When *Aspergillus* causes invasive disease, mortality rates are high (30–100%) and notably so for invasive and disseminated or CNS forms of the infection.^{187,377,539} In a review of English-language articles on *Aspergillus* infections in adult LTRs, the overall mortality rate was 53% (59 of 112); it was 24% (nine of 38) for tracheobronchial or bronchial anastomotic infections, 82% (18 of 22) in patients with invasive pulmonary disease, and 67% (two of three) for disseminated invasive infection.⁵²⁵ These published data reflect the limited therapeutic options previously available (before the advent of extended-spectrum azoles and echinocandins). Several more recent studies suggest an improvement in the mortality rate (40%) since the widespread use of voriconazole and TDM.^{36,417,573}

Despite the lack of controlled trials, several surveys document that most lung transplant centers use prophylactic or preemptive systemic antifungal agents (azoles, echinocandins, or amphotericin formulations), aerosolized amphotericin formulations, or both in patients with pre- or postoperative isolation of airway *Aspergillus*, and almost 60% of the centers employed universal prophylaxis.^{136,153,154,262,376,412,447} Because *Aspergillus* infections are acquired through the lungs and most infections are pulmonary, attaining high pulmonary drug levels via aerosolization and limiting systemic toxicity are attractive options for prevention.^{154,376,533} Multiple trials have suggested a reduction in IA with the use of aerosolized amphotericin formulations.^{68,86,154,155,159,234,389,394,431} A single retrospective study incorporating the use of universal voriconazole prophylaxis with or without inhaled amphotericin compared with targeted itraconazole in LTRs decreased the rate of IA at 1 year from 23.5% to 1.5%.²⁵⁶ Abnormalities in liver enzymes were common, necessitating discontinuation of voriconazole in 14% versus 7% of the comparator. This study was performed before widespread use of voriconazole TDM, the use of which may have precluded some of this toxicity. Based on two phase II studies, posaconazole is FDA approved for prophylaxis of invasive fungal infections in certain high-risk patient populations 13 years or older.^{114,573} Studies evaluating the use of posaconazole suspension prophylaxis in LTRs have demonstrated mixed results, including variability of perioperative posaconazole concentrations; serum correlating with BAL, but often both subtherapeutic; tolerability/adverse events requiring discontinuation (gastrointestinal upset, transaminase derangement); tacrolimus interactions; and IA breakthrough^{478,560} (15%). A novel targeted peritransplant antifungal strategy compared sequential cohorts in which all patients received inhaled amphotericin B deoxycholate (AmBD) during hospitalization, along with 7 to 10 days of micafungin.²⁹³ Only those with positive fungal cultures from intraoperative BAL cultures (cohort 2) received additional 3 to 6 months of targeted antifungal therapy (yeast or mold active); 19% of patients in the second cohort received additional antifungal therapy based on intraoperative cultures. Cohort 1 had 29 invasive fungal diseases, cohort 2 had 10.

The rate of IA was 4%, which is similar to institutions that use universal azole prophylaxis strategies. No patient in this group experienced antifungal drug–related toxicity or fungal-associated mortality. Further randomized, multicenter studies are needed to clarify which agents and prophylactic strategies are most effective.

Prevention of IA infection through environmental controls also is important.^{435,445,469,562} Infections with this fungus in transplant recipients can be nosocomial or community acquired. Most germane to prevention is air control, inasmuch as both epidemic and sporadic IA correlate with concentrations of *Aspergillus* in the air.⁹ A protective hospital environment should consist of high-efficiency particulate air (HEPA) filtration, positive air pressure, high air exchange rate, properly sealed rooms, and removal of carpets, plants, and water-damaged ceiling and floor tiles.^{115,156,222,445} Patients should be wearing “fit-tested” masks (N95) when leaving protected environments, efforts should be made to have construction barriers in place, and patient transport routes should be adjusted accordingly if construction is occurring in the hospital and clinics.⁴³⁵ In addition, monitoring the environment and air for changes in particulates and fungal spores may be considered based on local epidemiology, rates of IA, and infection control practices. When patients are discharged home, they should be counseled to avoid certain high-risk exposure to agents such as excessive dust and molds if possible.⁴⁴⁵

Candida

Although *Candida* infections are the most common cause of fungal infections in SOTR recipients, those patients at highest risk are abdominal transplant recipients (liver, small bowel, and pancreas), with LTRs at intermediate risk, and renal transplants at the least risk.^{410,516} The overall rate of *Candida* infections in LTRs has decreased over time, in one study from 20% (1980–86) to 1.8% (2001–04), as has attributable mortality from 39% to 15%.⁵⁰² *Candida* infections in LTRs generally occur early, within the first month after transplantation, and are associated with long-term broad-spectrum antibiotic therapy, the presence of central venous access and other indwelling foreign bodies, surgical complications, CMV infection, and renal replacement therapy.^{298,516} Infections present in the form of BSI often result from catheter-associated urinary tract infections, especially if the Foley catheter remains in situ, or respiratory tract infections (tracheitis, pneumonia, and rarely bronchial anastomosis site infections).^{502,516,576} Although colonization of the respiratory tract is a common occurrence, primary invasive candidal pneumonia is not. Invasion usually occurs when comorbid conditions are present.²⁹⁸ In patients with a fungemia, workup for metastatic sites, including ophthalmologic examination, echocardiography, and imaging, should be performed, especially if fungemia is persistent. Rarely disseminated disease of abdominal organs and the CNS can occur in SOTRs.⁴³⁸ The source of infection usually is endogenous, although contributions from donor organs and nosocomial transmission may also arise. A decline in *C. albicans* infections and a concomitant increase in non-*C. albicans* spp. has been demonstrated.⁴⁵⁴ Mirroring these changes, the Transplant Associated Infections Surveillance Network documented an increase in non-*C. albicans* candidal species, which was the driving force increasing azole resistance in *Candida* species (overall 16%), especially for *C. glabrata* and *C. krusei*.^{339,438} Of interest, the azole resistance of *C. albicans*, *C. tropicalis*, and *C. parapsilosis* remained relatively low (1%). In SOTRs, fluconazole resistance was associated with any fluconazole use in the 3 months before infection.

The diagnosis of *Candida* infections can be challenging and often requires differentiating colonization from infection because *Candida* spp. are ubiquitous, especially in the upper gastrointestinal and respiratory tracts. In addition, although the diagnosis is often made by culture, these techniques are insensitive, especially for invasive disease and, except for blood culture, nonspecific. If recovery of *Candida* spp. from BAL fluid is associated with respiratory symptoms or deterioration of lung function (e.g., increased sputum production), treatment should be considered, although other causes such as rejection and coinfections should be explored as well. Organisms should be identified to the species level because of species-specific susceptibility profiles.³³⁹ Early germ tube determination can confirm the presence of *C. albicans*, and a negative test can alert the physician to the presence of non-*C. albicans* spp., which may have an impact on the choice of antifungal agent.⁴³⁸

Newer molecular probes, such as peptide nucleic acid fluorescence in situ hybridization (PNA FISH), can identify *C. albicans* rapidly from positive blood cultures.¹⁰

The Fungitell (1→3)- β -D-glucan assay has been FDA approved as an adjunct for the diagnosis of invasive *Candida* and⁴³⁸ its role in the early diagnosis of these infections is still under investigation; it may be especially useful for the diagnosis of deep-seated candidiasis when blood cultures are known to be insensitive.^{416,438} Additionally culture-independent T2MR technology can detect *Candida* spp. (*albicans*, *tropicalis*, *parapsilosis*, *krusei*, *glabrata*) directly from patient's blood by amplification of DNA and identification to species level, by T2 magnetic resonance.^{403,457} Overall sensitivity in adult patients was 91%, with a mean time of 4.4 hours \pm 1 hour to identification. Its use in diagnosis, specifically in pediatric patients (it requires 3 mL of blood) and in transplant recipients, requires further study. The choice of initial antifungal therapy should be based on the patient's azole exposure, dominant species and susceptibility profiles at the institution caring for the patient, comorbid conditions, sites of involvement, and the use of other medications that might have significant drug–drug interactions.⁴³⁸ The IDSA guidelines for management of candidiasis recommend fluconazole or an echinocandin in most settings, the latter especially in ill patients with recent azole exposure, with transition to fluconazole when stable.^{239,438} Duration of therapy, as with other infections, should be individualized, but treatment should be continued for a minimum of 2 weeks after the last positive culture has been obtained and the signs and symptoms have resolved.⁴³⁸ As noted earlier for *Aspergillus* infections, issues of dosing in pediatric patients with the newer antifungal agents and drug–drug interactions should be considered. Several excellent resources are available for detailed treatment algorithms.^{438,516} Susceptibility testing should be considered on non-*C. albicans* spp. and for *C. albicans* infections that are refractory to conventional therapy. Interpretive breakpoints are available for most common antifungal agents including echinocandins.^{10,455,456} Although candidemia should always be treated with an antifungal agent, the issue of removal of indwelling catheters has been controversial because of the lack of randomized controlled data designed to answer this question. The 2016 IDSA guidelines for the management of candidiasis and catheter-related BSIs recommend early removal of catheters when the source is presumed to be the central venous catheter and the catheter can be removed safely; decisions to do so should be individualized.^{24,424,438}

Cryptococcus Neoformans and Gattii

Although relatively rare, cryptococcosis is the third most common fungal infection seen in SOTRs after *Aspergillus* and *Candida*, with an overall incidence of 2.8% (0.3% to 5%).⁵⁵⁶ Available data suggest infection is less common in pediatric patients than in adults.^{38,534} This infection usually occurs late, after the first year posttransplant, but it may occur earlier in LTRs.^{38,531,556} Disease can be newly acquired but most often in adults is reactivated from latent disease; cases of donor-derived infection have been documented.^{38,199,261,556,625} In the latter two scenarios, presentation may be within the first few months after transplantation.^{39,554,556} The overall incidence and time to onset had not changed over many decades, but there are notable shifts in the recent epidemiology. Patients with cryptococcosis are more likely to be LTRs or multivisceral transplant recipients as opposed to renal recipients. Although CNS involvement and dissemination, with or without fungemia, remains the most common presentation—in upward of one-half of SOTRs—the presentation of isolated pulmonary infection has become more common in SOTRs. This is especially true since the almost universal use of calcineurin inhibitors.^{133,261,522,556,590,625} These immunosuppressants target the fungal homologs of calcineurin, resulting in synergistic interactions with antifungal therapy and increased anticryptococcal activity and thus providing some protection against disseminated disease.^{201,261,291,522,523} On the other hand, steroids and T-cell–depleting antibodies, as induction therapy or especially for antirejection, are known risk factors for cryptococcal infection in SOT recipients.⁵⁹⁰ Pulmonary infections may have a variety of nonspecific presentations, including single or multiple nodules, infiltrates, consolidation, and pleural effusion; isolated pulmonary disease may be asymptomatic and detected as an incidental finding. Cutaneous disease manifests as nodular, maculopapular ulcers

or pustules or as cellulitis and may be a portal of entry but most commonly indicates disseminated disease; this finding requires a full evaluation of extent of infection including CNS involvement.⁵⁵³

The diagnosis can be made by culture, visualization of encapsulated yeast with India ink or other special stains, and testing for cryptococcal capsular polysaccharide antigen in serum or CSF.¹⁰¹ Although the serum cryptococcal antigen test is most reliable for CNS and disseminated disease (83%+), and a positive test should prompt a full evaluation, it is known to have decreased sensitivity for isolated pulmonary infection; indeed, among SOTRs, those LTRs with isolated pulmonary disease appear most likely to have negative cryptococcal serum antigen.^{553,590} BAL can be performed to identify yeast in the lungs. CNS imaging and lumbar puncture should also be performed with opening pressure and large-volume CSF removal on SOTRs with suspected/proved cryptococcosis.³⁸ The majority of infections are caused by *C. neoformans*, but *C. gattii* infections in SOTRs have also been recently described¹⁷³ and are recognized as an emerging infection in the Pacific Northwest since 2004. These infections were similar to *C. neoformans* with a high degree of dissemination/CNS at time of diagnosis, at a median time 17.8 months posttransplant. Patients with meningitis had low antigen titers (median 1:8) and less robust CSF inflammatory response. The minimum inhibitory concentration (MIC) for fluconazole was elevated (1 to 32 μ g/mL) and mortality was high (36% 90-day) in this cohort.

The IDSA guidelines for management for cryptococcal disease from 2010⁴⁵¹ recommend that the mainstay of therapy for severe, disseminated disease with CNS involvement is a combination of an LFAB plus flucytosine, which confers a survival advantage over conventional AmBd—11% versus 40% mortality in SOTRs.^{531,552} TDM should be performed for flucytosine to avoid drug toxicities of bone marrow suppression and nephrotoxicity. Combination induction therapy should continue for a minimum of 2 weeks, or 4 to 6 weeks if flucytosine is not used. An extended period of fluconazole maintenance therapy (6 to 12 months) is recommended because relapses are well documented, especially in HIV-infected patients. As noted earlier, increased MIC may be seen in *C. gattii* infections, and extended azoles may be an alternative in this setting.^{38,173} The risk for relapse in SOTRs and the optimal length of therapy are not known. Duration of treatment less than 6 months has been associated with an increased rate of relapse.^{451,521,531} Management of elevated intracranial pressure is essential and may require repeated, sometimes daily, lumbar punctures and, rarely, placement of a ventriculoperitoneal shunt.^{101,451} For less severe disease localized to the lungs, an oral azole alone may be adequate.^{173,451,531} Mortality rates for SOTRs have improved over time: the overall mortality rate for cryptococcal disease is reported as 11% to 30% and varies by site of infection, treatment regimen, type of transplant, and possibly immunosuppressive regimen. The highest mortality rates are seen in liver and kidney transplant recipients with disseminated disease or fungemia, or both (20–70%). The lowest mortality rates (3–13%) are seen in localized pulmonary disease.^{133,521,522,531,552,625}

Immune reconstitution inflammatory syndrome (IRIS) or immune reconstitution syndrome (IRS) is well described in cryptococcosis in SOTRs and correlates with treatment and the evolving host response to infection. Reversal of cryptococcal induction of T_H2 responses with antifungal medication and decreasing the iatrogenic immunosuppression leads to a proinflammatory milieu as T_H1/T_H17 responses are restored.^{451,521,529,530,555} This physiologic immune response can become pathologic in about 15% of transplant recipients. Criteria for IRIS in the transplant setting have been published and these include clinical findings occurring during receipt of antifungal therapy and in the absence microbiological persistence or negative cultures and without another explanation.⁵³⁰ Manifestations of IRIS include fever, lymphadenopathy, and progression of pulmonary and CNS symptoms and lesions, without documentation of increased titers or positive cultures. IRIS in SOTRs presents a mean of 6 weeks after initiation of therapy and correlates with this reduction of immunosuppression, which remains a cornerstone to therapy but should be done in a gradual, stepwise fashion to avoid rapid reconstitution.^{168,551} Risk factors for developing IRIS in SOTRs include disseminated/CNS disease (fungal burden), discontinuation of calcineurin inhibition (but not dose reduction or changes in other immunosuppressants), and graft rejection (greater degree of “immune

reconstitution”—inadequate T_{reg} response).^{168,530,551} These authors state that, based on observations including the potential benefit of calcineurin inhibitors to antifungal activity and the lack of association of the reduction of corticosteroids on the risk for developing IRIS, consideration should be given initially to tapering corticosteroids, followed by reduction but not discontinuation of calcineurin inhibitors. There is no established therapy for IRIS. Minor manifestations may resolve over time, but IRIS may be life-threatening in severe cases and can lead to graft loss.⁵³⁰ Increasing doses of corticosteroids have been used. Investigational therapies include statins to promote T_H2/T_{reg} over $T_H1/17$ pathways and tumor necrosis factor- α inhibitors.^{521,555}

Pneumocystis Jiroveci (Formerly *P. Carinii*)

Pneumocystis pneumonia (PCP) is caused by the renamed fungal pathogen *Pneumocystis jiroveci*. PCP has been associated notably with defects in T-cell immunity and with the immunosuppression used in SOTRs. In most cases, symptomatic PCP in an immunocompromised host is thought to be reactivation of latent infection, although putative nosocomial person-to-person transmission linked by molecular evidence is increasingly observed.^{134,125,319,462,499,504}

Heart-lung recipients and LTRs are at increased risk for developing infection, with reported attack rates of 6.5% to 43% without prophylaxis, up to a 10-fold increase as seen in heart transplants alone.⁴⁷⁹ Higher rates of infection in SOTR, including LTR, have been associated with CMV coinfection, use of cyclosporine and corticosteroids, and receipt of therapy for rejection; cases can occur many years after transplantation.^{400,462,504,601} Therefore guidelines recommend a benefit of long-term and perhaps lifelong prophylaxis, especially if additional risk factors are ongoing.^{479,504,601} The drug of choice for prophylaxis remains TMP-SMX, and its use is associated with dramatic decreases in the incidence of PCP infection. Additional benefits of this drug include prevention of many community-acquired respiratory, gastrointestinal, and urinary tract pathogens and protection against most *Toxoplasma gondii* and *Nocardia* infections. Multiple regimens exist, and dosing for 3 days per week appears to be as effective as daily dosing in all populations studied. Toxicity remains an issue for some patients and includes bone marrow suppression, decreased renal function, hepatitis, and rash (Stevens-Johnson syndrome), which may be severe. Details of alternative regimens are reviewed in Chapter 225 and elsewhere.^{479,504}

PCP infection is manifested as progressive dyspnea, cough, tachypnea, chest pain, and cyanosis over the course of days to weeks. In addition, fevers, sweats, and flulike symptoms may be prominent. Hypoxia and shortness of breath, in the context of normal or minimal findings on chest radiographs, are common findings. Corticosteroids and calcineurin inhibitors may alter the signs and symptoms and render early diagnosis more difficult to establish. The diagnosis is confirmed by identification of *P. jiroveci* in a respiratory sample or lung tissue. Immunofluorescent staining of organisms with monoclonal antibodies had been the technique of choice; Gomori methenamine silver nitrate, which stains cyst forms only (5% to 10% of the total organisms), is the most reliable staining method.⁴⁷⁹ BAL fluid and tissue obtained by open-lung biopsy have the highest diagnostic yield.⁴⁷⁹ Polymerase chain reaction (PCR) assays on BAL specimens are now recognized as highly sensitive and specific diagnostic techniques and are commercially available. This assay may allow the distinction between colonization and low fungal burden infection.^{8,70,225,497} (1 \rightarrow 3)- β -D-Glucan is a component of the *P. jiroveci* cell wall and can be detected in the serum of patients with PCP.^{116,143,292,501} This assay appears to be a reliable marker of infection, with the most convincing results shown in patients with HIV infection.¹⁴³ At this time, it cannot be recommended to supplant appropriate testing of respiratory samples, but it may be considered as an adjunct for diagnosis, especially in patients too ill to undergo invasive procedures.³⁹⁸

The mainstay of therapy for PCP infection remains high-dose TMP-SMX for 14 to 21 days.^{166,362} Corticosteroids are generally recommended for severe disease, including a 5- to 7-day course with a slow taper over 7 to 14 days. For patients intolerant of TMP-SMX or those less seriously ill, alternative therapies can be considered, including dapsone with trimethoprim, atovaquone, intravenous pentamidine, trimetrexate, clindamycin/primaquine, and pyrimethamine/sulfadiazine.^{166,362} Relapse in patients without HIV infection is an

uncommon occurrence with TMP-SMX therapy if a reduction in immunosuppression can be accomplished and coinfections such as with CMV do not occur.

Endemic Mycoses

Endemic mycoses, or the dimorphic fungal infections histoplasmosis, blastomycosis, and coccidioidomycosis, are rare but important causes of disease in SOTRs.^{279,385} There is a noted bimodal distribution in the onset of infection—within the first 6 months and again at more than 2 years after transplant (up to 11 years)—and therefore these infections should be considered in the differential at all time periods.²⁷⁹ Rejection does not appear to have a major role in development of endemic mycoses, in contrast to invasive mold infections, although it may be associated with increased risk of development of coccidioidomycosis. Spores are inhaled from the environment and convert to noncontagious yeast forms at 37°C. Infection may be caused by latent reactivated disease in the recipient or donor or may be newly acquired. Donor-derived infections generally manifest within the first several weeks after transplantation. Because of the nonspecific findings, latency of these organisms, increased worldwide travel, and organ procurement strategies, infections in transplant recipients require a high index of suspicion, especially if they occur in nonendemic areas. This is important because the response to therapy is generally excellent if appropriately initiated.²⁷⁹

Coccidioidomycosis, caused by *Coccidioides immitis* and *C. posadasii*, is the endemic mycosis most commonly seen after transplantation. It occurs in up to 9% of SOTRs in endemic areas of the southwestern United States (especially California and Arizona), northern Mexico, and Central America.^{63,584} Unlike histoplasmosis and blastomycosis, pretransplant infection poses an increased risk for development of serious posttransplant disease. Transplant candidates should be screened for a history of coccidioidomycosis and environmental exposure, which should prompt serologic testing for *Coccidioides*. Secondary prophylaxis is very effective and should be given to all patients with a history of *Coccidioides* infection; without its use, the mortality rate is very high (up to 70%).^{63,280,385,584} Pulmonary infections may be accompanied by an acute onset of respiratory symptoms and fever and progress rapidly to respiratory failure. Nonspecific symptoms of anorexia, weight loss, and fatigue may herald extrapulmonary disease. Dissemination to bones, skin, and the CNS occurs commonly when infection occurs in transplant recipients. The time of highest risk appears to be in the first 3 months after transplantation, with the majority of infections occurring by 1 year. Donor-derived coccidioidomycosis has been documented in LTRs.^{64,386,385,569,623} Recipients did not have evidence of pretransplant coccidioidomycosis, nor did they live or travel to endemic areas. Several of the donors had documented epidemiologic risk factors. Commonly these LTRs had fulminant pulmonary or disseminated infections within the first 3 weeks after transplantation, the majority of which were fatal.

The diagnosis of coccidioidomycosis can be made definitively by culture, usually from respiratory samples or urine and rarely from blood or CSF.²⁵ Histopathologic evaluation may reveal large spherules with the presence of endospores. Serologic tests include tube-precipitin antigen (IgM), detected early in disease, and complementation fixation or immunodiffusion (IgG), which can be titrated and is helpful in monitoring response to therapy.^{25,63} *Coccidioides* antigen testing may improve diagnostic sensitivity, especially in immunocompromised patients who may have negative serologic studies. Recent data suggest it is a useful addition to the diagnosis in meningitis as well.²⁷⁴ The optimal therapy for SOTRs with coccidioidomycosis is unknown but generally follows published guidelines.¹⁸² Patients with evidence of previous infection should receive secondary prophylaxis with azole therapy for a minimum of 6 to 12 months after undergoing transplantation.^{25,63,182,385}

Histoplasma capsulatum infection is a rare occurrence after transplantation, even in patients with presumed pretransplant infection. Cases in transplant recipients have been observed in endemic areas and in conjunction with outbreaks in areas hyperendemic for histoplasmosis, the Mississippi and Ohio River valleys, and Central America.^{120,577} Two cases of histoplasmosis in renal transplant recipients were linked by molecular typing to donor-derived disease.³²⁶ Several series of histoplasmosis in SOTRs have noted a high rate of dissemination, fungemia, and severe disease, although generally with good response to prolonged

therapy (12 months), although mortality rates were 10% to 13%.^{35,120,279} Median time to diagnosis was 17 months after transplant, and time from onset of symptoms to diagnosis was 3 weeks, reflecting the protean nature of initial presentation. Up to 50% of cases occurred within the first 2 years. Donor-derived infection has been documented by typing and usually presents in the first month after transplantation. Relapse occurred rarely, often many years after initial infection, and was associated with mortality in some cases. Several patients were identified with evidence of histoplasmosis in explant or donor tissues and received antifungal prophylaxis without developing active infection.⁶⁰⁹ Manifestations of infection include pulmonary, mediastinal, inflammatory, and disseminated syndromes with or without CNS involvement. The diagnosis can be made by culture, histopathology, serology, or antigen detection.⁶⁰⁹ In immunosuppressed patients with disseminated disease, culture of appropriately obtained specimen, and antigen detection (urine, serum, BAL) appear to be the most useful (sensitivity of 80% to 100% using third-generation assays).^{218,221} Antigenemia and antigenuria together likely is the most sensitive diagnostic approach in SOTR.³⁵ Cross-reactivity with *Aspergillus* and *Blastocystis* can result in false-positive *Histoplasma* antigen tests with these infections.⁵⁸² In addition, positive galactomannan antigen assays have been reported in SOTRs with histoplasmosis.⁵⁸² New enzyme immunoassay (EIA) antibody testing appears more sensitive than previous assays and allows for detection of IgM and IgG although data on use in immunocompromised patients is not available.⁴⁷⁵ Guidelines recommend long-term therapy (3 to 4 months) with LFAB for immunocompromised patients with disseminated or CNS involvement, followed by 6 to 12 months of itraconazole.^{385,610} Voriconazole and posaconazole have good in vitro activity and have been successfully used as well.^{177,178} Monitoring antigen levels is beneficial to assess response to therapy and for relapse.^{219,610}

Blastomyces dermatitidis, the causative agent of blastomycosis, appears to be the least common endemic fungal infection in the posttransplant setting.¹⁸⁶ These infections are rare events in series of fungal infections in immunocompromised patients, including patients with acquired immunodeficiency syndrome (AIDS), even in endemic areas of the south central and north central United States, particularly in the Ohio and Mississippi River valleys and around the Great Lakes.³⁸⁵ Cases of posttransplant disease most commonly present as pulmonary disease, which may lead to acute respiratory distress syndrome and a high mortality rate. Diseases of the skin and CNS are also common.^{278,508} Diagnosis is made by histopathology, culture, and antigen detection.^{100,111,385} Guidelines for therapy recommend that immunocompromised patients should receive LFAB until stabilized (4 to 6 weeks), followed by a prolonged course (6 to 12 months) of an azole.^{100,385} Most data are available for itraconazole, although voriconazole and posaconazole also may be effective.^{100,278}

Emerging Fungi

The impact of these emerging fungi for LTRs is increasingly appreciated. Published reports suggest that these infections are becoming more commonly recognized pathogens in LTRs and other SOTRs.* These organisms include non-*Aspergillus* hyalohyphomycetes or hyaline hyphae without pigment (*Scedosporium apiospermum*, *Fusarium* spp., *Pupureocillium/Paecilomyces* spp.); phaeohyphomycetes, or dematiaceous pigmented molds (*Cladophialophora bantiana*, *Alternaria* spp., *Curvularia* spp., *Scedosporium prolificans*, *Exophiala jeanselmei*, *Pyrenochaeta romeroi*, *Cladosporium* spp.); Zygomycetes, or nonseptated hyphae (*Rhizopus* spp., *Mucor* spp.); and yeast-like organisms (*Trichosporon*, *Malessezia*, *Rhodotorula*).²⁵⁰ These infections represent upward of 10% of fungal infections in SOTRs and should be considered along with IA. Lung and liver transplant recipients are at the highest risk for these infections. Risk factors include profound immunosuppression (in donor and/or recipient), exposure to azole therapy, breaks in skin integrity, and chronic lung disease. These infections tend to present late after transplantation, often after the first year, and have been associated with donor-derived infections utilizing organs from near drowning events and “commercial transplantation/transplant tourism,” which has been linked to poor posttransplant outcomes.¹⁹⁸ Many of these organisms are highly resistant

and have unique susceptibility profiles, which include the newer azoles voriconazole and posaconazole, as well as LFAB and terbinafine. The newest azole to be FDA approved for treatment of IA and mucormycosis, isavuconazole, has demonstrated some promise in treatment of mold infections.³⁸² Several recent studies offer evidence that isavuconazole demonstrates noninferiority to voriconazole for *Aspergillus* infections and has greater in vitro activity against these emerging pathogens.^{347,365} It is well tolerated, without dermatologic, ophthalmologic, and hepatic toxicity; has excellent PO bioavailability; and the intravenous formulation does not require solubilization by cyclodextrin. Frequent poor outcomes with mold infections has prompted the use of combination therapy as well, which is supported by some in vitro data,²⁷⁷ although clinical data are lacking and/or inconclusive at present.^{150,250,541} Indeed, these infections may be more likely to be disseminated and fatal than those caused by *Aspergillus* spp.^{151,250,251,365,385}

Surgical debridement may play an important role in therapy, in addition to medical therapy as well as decreasing immunosuppression and perhaps additional immune modulation with IFN- γ and/or GM-CSF.²⁵⁰

Donor-derived fungal infections are rare events, although well-documented serious complications can occur in SOTRs,⁵²⁴ as mentioned earlier. Most commonly recognized is donor-derived candidiasis in renal transplant recipients; intestinal perforation in the donor has been identified as a risk factor. Other infections, such as cryptococcosis from unrecognized cryptococcal meningoencephalitis in donor and endemic fungal pulmonary infections in undiagnosed/asymptomatic donors, have occurred. Even less common, although with great consequence, are donor-derived mold infections such as aspergillus and mucormycosis, with high mortality rates. Source of infection can be from donor allograft or contaminated preservation fluid. Allografts should be carefully examined for granulomas or other unusual findings. All potential donor-derived infections should be reported to the Organ Procurement and Transplantation Network. This is especially important if organs from a donor have gone to multiple recipients, so the epidemiologic link can be documented and therapy or prophylaxis can be initiated to other recipients in a timely manner. The American Society of Transplantation has developed guidelines to enhance the ability to identify donors with risk factors to transmit fungal infections, although data to address all issues are lacking.

Viral Infections

Cytomegalovirus

The epidemiology of CMV infection in SOTRs has changed in recent years. Advances in diagnosis and in preemptive and prophylactic strategies and therapy have decreased the impact of early CMV infection in transplant populations. However once antiviral medication is discontinued, CMV infection is common in high-risk patients, and it remains one of the most important pathogens in SOTRs, with wide-ranging effects on morbidity and mortality.^{131,248,249,391} Thus continued efforts to optimize preventative strategies are paramount.^{391,433,444} The source of infection can be endogenous reactivation or from the donor graft or leukocyte-containing blood products and cause primary infection or reinfection. Rarely primary infection may be acquired from the community, especially in young children.

The effects of CMV infection have both profound direct and indirect consequences. As per published definitions, direct effects of the virus range from “asymptomatic” CMV infection, which can be detected by viremia (culture positive), antigenemia (pp65 in leukocytes), and DNAemia or RNAemia (generally by quantitative PCR methods or quantitative nucleic acid amplification testing [QNAT]); to CMV syndrome with viremia, fever, neutropenia, thrombocytopenia; to true end-organ disease, which is often found primarily in the allograft but may disseminate.^{295,471} The diagnosis of end-organ disease, such as pneumonitis, enteritis/colitis, hepatitis, and encephalitis/meningitis, requires signs or symptoms of disease at that site, with detection of CMV by culture, histopathology, immunohistochemical staining, or in situ hybridization. Except for CNS disease, detection by QNAT is not sufficient for establishing the diagnosis because it is too sensitive and may signify transient viral shedding. Investigation regarding the use of CMV QNAT, including the appropriate specimen (plasma or whole blood) and establishing international standards and thresholds for

*References 151, 250, 251, 307, 370, 390, 448, 494, 509, 517, 546.

therapy are ongoing. Data support the use of plasma for testing, which is likely equivalent to whole blood in determining undetectable viremia and risk of relapse despite the increased sensitivity of the later specimen. In addition, in 2010, the first World Health Organization (WHO) International Standard for Human Cytomegalovirus for Nucleic Acid Amplification Techniques was released as a tool that can be used to standardize patient results from different sites and using different assays.^{179,226,272}

Data from different sites are now available to validate the use of international units (IU) in quantitative measurements of CMV DNAemia (calibrate and establish colinearity to reference material), which may help future multicenter studies to delineate testing algorithms, define relevant cutoffs and testing frequencies, and further clarify clinician guidance and patient outcome.^{236,354,470,491}

The indirect, immunomodulatory effects of CMV have broad-reaching consequences and can be divided into three categories: (1) immunomodulation as it contributes to the net state of immunosuppression and increased risk for opportunistic super infections (e.g., aspergillosis, PCP); (2) increased risk for oncogenesis, such as seen with EBV-related lymphoproliferative diseases; and (3) allograft injury and dysfunction, as seen in classic rejection and vasculopathy of the allograft. In LTRs, BOS, a severe form of chronic rejection (small airways disease), has been associated with CMV infection.^{336,488,631} Of interest, in a retrospective, multicenter study of almost 600 pediatric LTRs, development of BOS in the first year (14%) was not associated with CMV infection.¹³¹

The greatest risk factor for developing CMV infection in children, as in adults, is donor/recipient (D/R) seropositivity, most notably D⁺/R⁻ mismatch, followed by D⁻/R⁺ mismatch. Infection can occur in D⁺/R⁺ and rarely in D⁻/R⁻ matches.^{126,131} Other risks include the use of induction therapy, antilymphocyte antibody, and blood product transfusion (performed previously).^{631,633} In pediatric LTRs, the risk for CMV infection has also been associated with living donor transplant, older age at transplant, and multiple episodes of A2 rejection before CMV.¹³¹ The incidence of CMV infection in LTRs is higher than that in other SOTRs. The reasons are multifactorial but include long-term, intense immunosuppression and high levels of CMV latency, viral load, and reactivation associated with the lung and its transplantation.^{43,633} The incidence of infection and disease is reported to be 54% to 92% without prophylaxis.^{631,633} The rates of CMV infection and its consequences have been considerably decreased by utilizing various preventative strategies (see later discussion), although different study design, endpoints, and follow-up periods point to the difficulty in identifying the optimal regimen and time course.^{131,433,444,631}

A combination of approaches is employed to reduce the incidence of CMV infection. The use of CMV-negative or leukocyte-free blood products for CMV-negative recipients is standard practice in most transplant centers and has been shown to reduce infection rates. Matching of D/R serologic status probably would reduce infection rates but also would limit the donor pool for recipient-negative recipients significantly and is not considered to be indicated. The final strategies use different regimens of antivirals to suppress replication with or without immunoglobulin products for enhanced passive immunity.^{488,631} These regimens can be prophylactic, in which all patients at risk are treated for a certain period, universal prophylaxis (UP), or preemptive therapy (PET), in which highly sensitive screening techniques, such as antigenemia (pp65) or QNAT, are used to identify patients needing therapy. The rationale of this approach is to limit drug exposure, thereby decreasing toxicity and viral resistance. To complicate matters, regimens can include multiple antiviral agents, such as intravenous ganciclovir or acyclovir and/or oral ganciclovir, acyclovir, or valganciclovir for various periods. Most of the studies discussed here are performed primarily in adult transplant populations; pediatric recommendations are extrapolated from these data. Several surveys of lung transplant centers show a preponderance of the use of UP, based on serostatus stratification, although in a recent survey one-third of centers now use a hybrid combination of early UP followed by PET based on risk.^{127,196,312} Centers used a variety and combination of antiviral agents, although intravenous ganciclovir and/or valganciclovir were most commonly used; interestingly, underdosing in adults was common. Oral valganciclovir has been demonstrated to be noninferior to intravenous ganciclovir in adult SOTRs for eradication of viremia and long-term clinical outcome.³²⁻³⁴ Side effects and

discontinuations were also comparable. The dosing of ganciclovir and especially valganciclovir in pediatric patients is still evolving. There are now several published algorithms based on achieving the target ganciclovir area under the curve (AUC) of 40 to 60 $\mu\text{g} \times \text{h/mL}$ (protective for CMV infection in adults), although target levels were not initially achieved (ranging both above and below target) in up to 40% to 60% of children.^{31,285,453,548,549,591} The optimal algorithm and sampling strategy are yet to be determined. TDM is suggested to improve outcome and decrease toxicity. The recommendation for the duration of prophylaxis, especially in high-risk patients, has increased over the past 5 years (see later discussion), and the most recent survey suggests that most international centers now extend UP for a median of 6 months (range, 3 to 12 months) for D⁺/R⁻ LTR. In addition, few responding centers (16%) now use CMV intravenous immunoglobulin (IVIG) with variable schedules, although the benefits of its use remain unproved.^{67,468,630,634}

Methods and regimens for viral monitoring also varied greatly. These surveys highlight the need for additional data, some of which are now available, including a randomized controlled trial comparing 3 versus 12 months of valganciclovir in adult LTRs.^{433,612} This study and others provide evidence that, for high-risk LTRs, UP and extending prophylaxis beyond 3 months to 12 months and possibly “indefinitely” has an overall beneficial effect in terms of CMV infection and its consequences.^{131,191,248,391,433,444,612,634} A cohort of LTRs who received extended UP (12 months) were followed for an additional 3.9 years.¹¹² Patients who had received extended-course UP had a sustained proactive benefit with a lifetime CMV incidence of 12% versus 55% ($P = .009$). No long-term adverse hematologic effects were documented. Other retrospective, single-center reviews of SOTRs who received 6 months versus “indefinite” (minimum, 12 months) UP failed to show a similar long-term benefit and reported leukopenia (55% and 66%, respectively), some requiring discontinuation; ganciclovir resistance occurred in a small but notable number of patients, including fatal infections.^{49,612}

Although increasing the length of prophylactic antiviral therapy may decrease the incidence of CMV infection, additional complexity relates to the resultant immature T-cell response associated with long-term and potent antiviral suppression, whereas some “escape” may allow a protective T-cell response after therapy is discontinued.⁴⁸⁸ In addition, the concern remains for the creation of drug-resistant CMV infection in the presence of long-term antiviral exposure. Rates of resistant CMV remain relatively low in spite of broad use of antiviral agents for prophylaxis, although they are highest in LTRs among the SOTRs; this is believed to be secondary to intense immunosuppression and high viral load associated with lung tissue.^{433,612} A study in high-risk adult renal transplant recipients documents a higher incidence of drug-resistant isolates in preemptive strategies designed to decrease drug exposure.¹¹⁸ This supposed contradiction may be explained because the higher viral loads were seen in these patients, because by definition they were viremic before antiviral agents were initiated, and because of the use of oral valganciclovir, rather than intravenous therapy, during periods of high replication; all are risk factors for resistance.¹⁶⁷

Several evidence-based consensus guidelines by expert advisory groups on the management of CMV infection in SOTRs have been published and are summarized here^{295,471,633}:

- 1a. All D⁺/R⁻ or R⁺ LTRs should be considered for CMV prevention (UP or PET).
- 2a. Prophylaxis should continue for a minimum of 180 days, although some pediatric experts would limit this to 3 months given the risk for catheter-associated infection if intravenous ganciclovir is used.
- 2b. The drug of choice for prophylaxis is intravenous ganciclovir or oral valganciclovir.
- 3a. Monitoring should be performed every 2 weeks for the first 6 months after transplantation to assess for breakthrough viremia and disease and then periodically for 8 to 12 weeks after completion of prophylaxis.
- 3b. Whole-blood assay is the monitoring method of choice and should be validated at each center.
- 3c. If a PET approach is being used, CMV monitoring should be performed more frequently.
4. Breakthrough disease should be treated with ganciclovir 5 mg/kg administered intravenously every 12 hours for up to 21 days until

the viral load is below detection. Immunosuppression should be reduced if possible.

5. Infection that occurs after the initial prophylaxis has been stopped should be treated with ganciclovir or valganciclovir until the viral load is below detection.
- 6a. Resistance should be considered in patients with breakthrough viremia, recurrent infections, or poor response to therapy; persistent viremia at 21 days. Genotypic analysis for common mutations (UL97 [viral kinase] and UL54 [DNA polymerase]) should be performed on isolates recovered from these patients.
- 6b. Foscarnet is the drug of choice, with or without ganciclovir, for possible resistant strains.
7. Reinitiation of prophylaxis should be considered in patients requiring antilymphocyte antibodies or high doses of corticosteroids for rejection.

Of note, valganciclovir is not FDA approved for prophylaxis in LTRs, although it is for other SOTRs, and available data suggest that it is safe and effective in LTR as well.^{248,391,433,612,633} Data in pediatric patients for the safety and efficacy of valganciclovir for prophylaxis and treatment are emerging. Some preliminary data on formulations and pharmacokinetics are available and support concerns for underdosing, leading to resistance and some hematologic toxicity.^{87,360}

Epstein-Barr Virus/Posttransplant Lymphoproliferative Disorder

The disease manifestations of primary EBV infection in SOTRs range from uncomplicated mononucleosis (fever, malaise, exudative pharyngitis, lymphadenopathy, hepatosplenomegaly, atypical lymphocytosis) to conditions indistinguishable from malignant lymphoma. Organ-specific disease may include pneumonitis and hepatitis, as well as gastrointestinal, CNS, and hematologic involvement. Early lesions of EBV-driven lymphoproliferation, such as plasmacytic hyperplasia, are seen in mononucleosis-like syndromes within the context of normal tissue architecture. The term posttransplant lymphoproliferative disease (PTLD) is generally reserved for proliferation of EBV-positive immunoblasts and atypical lymphocytes associated with effacement or destruction of normal tissue architecture. The reader is referred to several excellent, in-depth reviews and guidelines.^{15,211,465}

The manifestation of EBV/PTLD is varied and depends on the site of involvement, which may be intrathoracic, extrathoracic (abdominal, head and neck, CNS), or disseminated and intranodal or extranodal.³²⁵ Often PTLD is seen in the allograft, as with lung, liver, and intestinal transplantation.²¹¹ Signs and symptoms of PTLD can be nonspecific, such as fever of unknown origin, malaise, weight loss, and sore throat.⁷² Abdominal pain, gastrointestinal bleeding, intestinal obstruction and perforation, allograft dysfunction such as changes in respiratory status in LTRs, diffuse lymphadenopathy on physical examination or CT, or hepatosplenomegaly should raise the index of suspicion for PTLD. Focal neurologic findings also can be seen with CNS disease. An additional challenge is to differentiate allograft rejection from PTLD; both entities in LTRs may be characterized by allograft dysfunction with diffuse consolidation on imaging, without obvious lymphadenopathy or a mass. Because the therapies for these two conditions are diametrically opposed, increasing or decreasing immunosuppression, this distinction obviously is critical.^{15,210}

Risk factors for the development of PTLD have been identified.^{15,72,109} Pretransplant EBV seronegativity (as a surrogate marker for the risk for development of posttransplant primary EBV infection) is probably the most important predisposing factor for the development of PTLD. Because primary EBV infection occurs almost universally by the time of adulthood, older individuals are already immune, and young children undergoing transplantation are therefore at greatest risk. Presumably it is the lytic phase of the primary EBV infection that sets the stage for PTLD because the delayed EBV-specific cytotoxic T lymphocyte (CTL) response observed in immunocompromised children allows for high viral loads and uncontrolled B-cell infection, latency, and reactivation.¹⁵ In addition, concomitant CMV infection or CMV mismatch before transplantation increases the risk for developing PTLD, contributing to the “net state of immunosuppression.” Certain immunosuppressive regimens, such as the use of OKT3 and polyclonal antilymphocyte antibodies and possibly tacrolimus in pediatric patients, are linked to

the development of PTLD, although it is likely that the overall intensity of immunosuppression, not a specific agent, is most important in defining the risk for development of PTLD. Indeed, EBV DNAemia may be a marker for “over immunosuppression” and is associated with subsequent occurrences of other opportunistic infections in LTR.⁵¹⁵

Patients at highest risk by type of transplant are small bowel recipients, followed by recipients of hearts and lungs and livers. This risk is probably multifactorial and includes more intense immunosuppressive regimens and transplantation of large amounts of lymphoid tissue with the graft, thereby increasing recipients’ potential exposure to donor-derived EBV. The published incidence of PTLD in pediatric LTR ranges from 7.7% to 26.3%.^{72,109,459} PTLD most often occurs within 12 months after transplantation, with median onset of primary infection at 6 weeks and symptoms presenting in the 2- to 3-month range.^{15,72} When late PTLD occurs, it is associated with older recipients, long duration of immunosuppression, EBV-negative disease, and poorer prognosis.^{15,109,313}

The diagnosis of PTLD requires a high index of suspicion. The gold standard is histopathologic examination of tissue. Specimens should be processed by pathologists familiar with the morphologic classifications (e.g., phenotype, lineage, clonality) and ancillary tests that may be helpful, such as tissue staining for EBV-encoded RNA 2 by in situ hybridization (EBERS), which is more sensitive than in situ targeting viral DNA or the use of immunohistochemical staining of latent antigens (EBNA-1 and 2, LMP-1) and more specific than EBV DNA amplification; the expression of CD20, which has implications for therapy, should also be determined.^{15,465} Imaging also can be used for presumptive diagnosis, to guide biopsy, and for follow-up.^{459,513} In LTRs, CT of the chest may reveal discrete nodules, air space consolidation, or mediastinal lymphadenopathy. Extrathoracic involvement is less common but may include abdominal lymphadenopathy, liver and spleen lesions, and a thickened bowel wall. Head and neck imaging may reveal involvement of cervical lymph nodes, pharynx, orbit, sinus, and rarely the brain. Fluorodeoxyglucose-labeled positron emission tomography combined with CT (FDG-PET/CT) in adult and pediatric SOTRs with PTLD may offer a more nuanced approach to diagnosis and staging and may be particularly helpful in management to distinguish between active versus necrotic/fibrotic lesions.^{57,61,346,579}

Viral load determination (quantitative PCR) from blood should be sought in patients with a concern for PTLD. Although an elevated load may support the diagnosis, the value of a single measurement is uncertain; no diagnostic threshold level has been identified. In addition, these assays are not standardized, and many questions remain regarding their use, including which compartment is most revealing and should be sampled (peripheral blood lymphocytes, whole blood, or serum), extraction methods, thresholds for initiation of therapy, and the effect of serostatus on the sensitivity and specificity of viral loads.^{15,207,210,276,309,465} Because of significant interlaboratory variability, longitudinal testing of patient samples should be performed at a single site. Finally not all patients with EBV/PTLD have elevated viral loads, and viral loads may be elevated without evidence of disease; therefore PCR assays lack sensitivity and specificity for PTLD.^{15,60} Although these assays are now widely used at transplant centers, further controlled studies are necessary to optimize their use in immunocompromised patients and to establish international standardization of viral load assessments, as with CMV.

Patients at the highest risk for PTLD and mortality are those in whom primary EBV infection develops early after transplantation; therefore every effort should be made to identify these patients. Pretransplant serologic assessment of donors and recipients for both EBV and CMV can alert physicians to most of these high-risk patients because donor-recipient mismatch of either virus appears to play an important role in risk stratification.^{72,109} Once identified, these patients should be monitored by PCR assay for evidence of primary infection, and careful examination and use of CT for early diagnosis of disease should be included. Several strategies have been used for the prevention of EBV/PTLD in high-risk patients.²¹¹ The use of EBV-negative donors, although probably effective, would reduce the donor pool substantially and generally is not advocated. The use of prophylactic antiviral therapy has not been proved to prevent the development of PTLD. Although these agents are active against the lytic viral infection that precedes PTLD, they are not active against the latent viral phase that characterizes

PTLD. Theoretically antiviral agents may decrease the number of newly infected cells, thus impacting viral loads. Acyclovir and ganciclovir are often used for prevention of CMV, and comparisons of the incidence of PTLD in certain high-risk patients receiving these antiviral agents suggest some benefit; however PTLD has developed in some patients while receiving these agents.^{132,180} A small prospective controlled study of high-risk (D⁺/R⁻) pediatric renal transplant recipients found valganciclovir prophylaxis to significantly reduce the incidence of primary EBV infection, lower viral loads in those who became infected, and less symptomatic disease associated with infection but did not investigate the link to PTLD.²⁴³ The use of IVIG or CMV IVIG is similarly a potential but unproved strategy.^{209,210,247} Given insufficient evidence, universal and routine use of antiviral agents and IVIG products for prophylaxis and preemption has not been endorsed by the American Transplant Society.¹⁵

Preemptive strategies aimed at identifying primary infection by blood PCR monitoring have received significant attention.* In these protocols, high-risk patients undergo EBV quantitative viral load monitoring at frequent intervals (usually weekly) to identify increases associated with infection, which is a prerequisite for the development of EBV/PTLD. Patients with a persistently high viral load should be evaluated aggressively for the presence of PTLD on examination and imaging, and suspicious lesions should be sampled. When the diagnosis of PTLD is made, immunosuppression should be decreased as much as feasible, the optimal duration of which is uncertain.^{15,316} Most patients with nonmalignant lesions will respond to this maneuver alone. Return to higher levels of immunosuppression is usually prompted by rejection or clear evidence of clinical and virologic response. The use of antiviral agents in this setting has become routine, although without proven benefit.¹⁵ Surgical resection and local radiation therapy may be beneficial for localized disease and in the event of gastrointestinal involvement. Characterization and outcome of patients with chronic high viral loads without evidence of PTLD is emerging. These studies suggest that up to 45% of patients will progress to PTLD up to 8 years after transplant.⁶⁰ Efforts to immunologically define and identify this high-risk group are ongoing.^{343,344} Risk factors for poor outcomes include poor performance status, multisite disease, CNS involvement, T- or NK cell- and EBV-negative PTLD, monoclonal disease, and presence of certain oncogenes or tumor suppressor genes.¹⁵

Monoclonal B-cell antibody therapy has become an attractive option for CD20⁺ lesions not responsive to a reduction in immunosuppression.^{15,465} The currently available product is an anti-CD20 antibody (rituximab). Reports document initial response rates of 40% to 60%, although relapses are not uncommon.^{62,105,106,207,387,423} A PTLD-specific prognostic index identified high-risk patients with a 0% 2-year survival, in contrast to 50% in intermediate and 88% in low-risk adult patients receiving rituximab for PTLD; this highlights the potential heterogeneity of the patients and outcomes.¹⁰⁶ These high-risk patients all required additional chemotherapy, and 55% died of PTLD. Although generally well-tolerated, long-term hypogammaglobulinemia is a common occurrence in recipients, and viral complications, such as severe CMV and hepatitis B and C infections, as well as parvovirus B19-induced aplasia and enteroviral meningoencephalitis, have been associated with its use.⁴⁶⁵ For refractory disease, cytotoxic chemotherapy may be indicated, in consultation with oncology colleagues. Small studies on pediatric SOTRs suggest that the combination of low dose chemotherapy and rituximab may be safe and effective.²¹⁵ Unfortunately even patients who respond to reduction of immunosuppression and do not have progression of PTLD, mortality may be high, secondary to chronic allograft rejection.³⁹⁹ The preliminary data on the use of adoptive immunotherapy (autologous and allogeneic EBV-specific cytotoxic T lymphocytes) show promising expansion, persistence, and efficacy of cytotoxic lymphocytes.^{223,500} The generation of calcineurin-resistant T-cell clones is expected to improve the performance of cytotoxic lymphocyte therapy in the presence of ongoing immunosuppression.⁷⁴ Other investigational therapies include immunomodulatory therapy (anti-interleukin-6, T_H1 response with IFN- α), interruption of viral signaling pathways (LMP1, LMP2a), and vaccine technology.^{15,207,224,465}

Other Herpesviruses: Herpes Simplex Viruses Types 1 and 2, Varicella-Zoster Virus, Human Herpesviruses Types 6, 7, and 8

Infections with herpes simplex virus (HSV) types 1 and 2 are common occurrences in SOTRs; in older children and adults, HSV usually is a reactivation disease manifested as orolabial or genital disease. Primary disease occurs in young children who contract the infection from viral shedding of close contacts or from allograft. Serostatus of transplant candidates should be determined because symptomatic reactivation occurs in up to 68% of seropositive SOTRs not receiving prophylaxis, especially in the setting of treatment for rejection, and naïve recipients are at risk for severe and prolonged primary infections given their lack of immunologic memory. In LTRs, serious or disseminated disease such as esophagitis, hepatitis, keratitis, pneumonitis, and severe disseminated and/or CNS infection can occur.^{538,613} Infections tend to occur early, within the first month after transplantation, unless prophylaxis is used. As with other herpesviruses, concomitant infection with CMV is not an uncommon event. The diagnosis can be made clinically when typical lesions are present. Culture and PCR technology can confirm the diagnosis and be helpful for unusual manifestations. PCR, which has replaced culture as the preferred test, has advantages of rapidity, increased sensitivity (fourfold higher than tissue culture), and identifying HSV in blood and other body fluids. Prophylactic strategies with acyclovir or ganciclovir used for CMV (3 to 6 months) can prevent HSV. Generally prophylaxis for HSV infection does not need to be continued past the early transplant period unless there are frequent clinical recurrences, in which case suppressive antiviral therapy should be continued until reduction of immunosuppression can occur. Occasionally lifelong suppression may be necessary. Intravenous acyclovir and oral valacyclovir or famciclovir are effective therapies for localized mucocutaneous disease. More severe disease should be treated with intravenous formulations until resolution of symptoms. Resistance of HSV in SOTRs is rare, but when it is suspected in instances of clinical failure, culture and susceptibility should be performed. Most resistance results from changes in the viral thymidine kinase gene.⁴⁶¹ Foscarnet, which does not require this viral gene for phosphorylation, is usually the drug of choice. Less frequent mutations with altered DNA polymerase may require cidofovir. A new lipid ester of cidofovir, CMX001 (brincidofovir), which has broad and potent antiviral activity and less toxicity, is currently in phase III trials for treatment of several DNA virus infections.^{138,466}

Primary varicella-zoster virus (VZV) infection can occur in pediatric LTRs, as can reactivation of previous disease leading to herpes zoster. The rates of VZV infections in SOTRs are not known, but presumably the infection rate after transplantation is low since the widespread use of varicella vaccine (Varivax), as it is in the general community.²⁰ Because VZV infection is a vaccine-preventable disease and complications of primary infection can be life-threatening, all patients should be screened for evidence of immunity, and seronegative transplant candidates should receive varicella vaccine.^{2,128,452} Available data demonstrate that this vaccine is safe and effective in this setting, although seroconversion rates may be reduced. Optimally, two doses 4 to 6 weeks apart and a minimum of 2 to 4 weeks before transplant should be administered. If the vaccine does not prevent disease, it should mitigate development of severe disease. In addition, susceptible family members also should receive the vaccine.

Exposure in posttransplant patients should be treated with a high-titer varicella immunoglobulin preparation if available (VariZIG); IVIG is recommended based on the "best judgment of experts" if high-titer preparations are not available, although no clinical data document its efficacy. The window for benefit of administration of immunoglobulin preparations is up to 10 days after exposure.^{20,93} Additionally some experts recommend the use of prophylactic acyclovir if exposure such as household or intimate contact is likely to lead to development of disease or is revealed past the window for immunoglobulin prophylaxis to be effective. Varicella vaccine, which is an attenuated live viral product, generally is not recommended in LTRs at this time.¹²⁸

VZV infection in LTRs should be treated with intravenous acyclovir until all lesions are crusted and the patient's symptoms have lessened.⁴⁵² Patients taking corticosteroids, especially during the incubation period, are at increased risk for the development of severe disease. Hemorrhagic and disseminated disease, including encephalitis, hepatitis, and

*References 15, 42, 51, 158, 207, 211, 465, 482, 547, 571.

pneumonitis, can occur in immunocompromised patients. All patients admitted to the hospital with VZV infections should be placed in combined airborne precautions; immunocompromised patients may shed virus for a prolonged period. Hospitalized LTRs who have received immunoglobulin post exposure prophylaxis should remain in isolation from day 10 to day 28.⁴⁵²

Herpes zoster is a common event in adult transplant recipients; rates in children have not been determined. A study of SOTRs aged 16 to 74 years found a 15% incidence of herpes zoster in LTRs, with a mean time to onset of 14 months and a median of 9 months (9 days to 5.8 years).²⁰⁴ The diagnosis is made clinically and with the use of viral culture or PCR techniques if necessary. Infections can become disseminated, as evidenced by multiple dermatomal spread, and should be treated with intravenous acyclovir and pain control. The use of corticosteroids should be decreased, if possible.

HHV-6 variants A and B, the latter of which is most commonly implicated in human disease, is an emerging opportunistic viral pathogen. Seropositivity reaches nearly 100% in early childhood and therefore disease in all but the very youngest transplant recipients probably represents reactivation. Several studies have documented HHV-6 by PCR assay or culture in a majority (66–90%) of apparently asymptomatic adult LTRs.^{268,320} Infections occur early after transplantation (median, 6 and 18 days) and can occur in the setting of CMV antiviral prophylaxis. Most are without obvious clinical manifestations that could be ascribed to HHV-6 alone.³¹¹ HHV-6 DNA can be recovered from BAL fluid in 20% of LTRs and often is found with other pathogens, including other herpesviruses.³¹⁰ In immunocompromised patients, HHV-6 may exert direct and indirect effects on the host. It probably is responsible for rare cases of encephalitis, hepatitis, pneumonitis, febrile illnesses, and bone marrow suppression.³²⁰ The presence of HHV-6 alone or as a cofactor to CMV may augment the immunomodulatory effects and increase the risk associated with fungal and other infections, as well as allograft rejection, BOS, and mortality.^{268,310,311,379,414} Many questions regarding HHV-6 in this population remain unanswered. PCR assay of peripheral blood lymphocytes is the most sensitive method for detection of virus, but it cannot differentiate between latent and active virus. Therefore detection of infection generally requires exclusion of other etiologies before causality can be ascribed to HHV-6 for clinical findings. Routine monitoring of asymptomatic patients is not recommended. Data are insufficient to recommend prophylactic or preemptive therapies, although the virus is susceptible to achievable levels of ganciclovir, foscarnet, and cidofovir. Treatment with these drugs may be considered in patients with compatible syndromes if other causes are eliminated and reduction in immunosuppression has not led to clinical improvement.³¹¹ Whether asymptomatic patients with documented HHV-6 infection would benefit from therapy with regard to the indirect effects of the virus remains unknown. Finally HHV-6, unique in the herpesvirus family, can rarely be chromosomally integrated as a mechanism of latency (CIHHV-6).⁵⁶⁷ It is estimated to occur in 0.8% of the normal population. Because the viral DNA integrates into every nucleated human cell, CIHHV-6 is characterized by extremely high viral loads (>1 million copies/mL blood), which may not indicate active infection. This has been described in SOTRs, although the significance of this occurrence is unclear.³¹⁵ Although some patients received antiviral therapy because of the concern of high titers, none had perceivable decline in their viral loads and those who did not receive therapy remained clinically asymptomatic. For this reason, the finding of CIHHV-6 may lead to unnecessary antiviral therapy.

The role of HHV-7 and HHV-8 in SOTRs is undefined. HHV-7 behaves in a similar manner as HHV-6 in normal hosts, although it appears to be less prevalent and occurs later in life. Symptomatic disease is less well characterized, but it may be responsible for similar syndromes seen with HHV-6 in normal children and transplant recipients.³¹¹ Evidence of HHV-8 infection in normal children is rare. It is associated with Kaposi sarcoma in immunocompromised patients, as well as body cavity lymphomas, PTLT, and Castleman disease.^{17,311} It also may be associated with fever and bone marrow suppressive syndromes of donor origin in transplant recipients.³⁴² Therapy includes reduction of immunosuppression and/or the use of mammalian target of rapamycin (mTOR; rapamycin/sirolimus) in the place of calcineurin inhibition for its

antiproliferative effect. Surgical excision, chemotherapy, and radiation may also be necessary.³¹¹

Community-Acquired Respiratory Viruses: Respiratory Syncytial Virus, Parainfluenza Virus, Human Metapneumovirus, Influenza, and Adenovirus

The paramyxoviruses respiratory syncytial virus (RSV), parainfluenza virus (PIV), and human metapneumovirus (hMPV) are common causes of upper and lower respiratory tract disease in normal children; symptoms range from congestion and rhinorrhea to laryngeal tracheobronchitis (croup), bronchiolitis, and pneumonia.^{17,18,21,22} Similar clinical syndromes can be caused by a variety of viruses, and LTRs may have atypical presentation; thus testing should remain broad until a diagnosis is made.³⁵⁵ Data on the impact of these viruses on LTR are emerging. Respiratory viral illness is encountered commonly after pediatric lung transplantation and can be severe and persistent. Coinfection and sequential infection with other respiratory viruses, CMV, and fungal pathogens occurs.¹⁹² A decreased 1-year survival was associated with respiratory viral illness, but not at 2 years in retrospective studies of pediatric LTRs.^{333,334} Neither study found an association with BOS, in concordance with some studies, although others have found associations with viral respiratory infections and acute and chronic rejection/allograft dysfunction (BOS) in LTR.^{255,301} thus this remains an area of ongoing investigation.^{241,355,388,593} Risk factors for respiratory viral illness and severe courses/complications among SOTRs include young age, lung transplantation, and CMV infection. Transmission occurs person to person, from exposure to infected nasopharyngeal secretions, and from fomites. Consideration should be given to screen recipients for incubating respiratory viruses before they undergo transplantation, especially if high levels of circulating virus are present in the community or illness is present in family members. Immunocompromised patients can shed infectious virus for long periods. Strict adherence to hospital infection control practices is most important in reducing nosocomially acquired disease from infected patients, visitors, and health care workers.³⁵⁵ Patients and their families should be counseled on avoidance of exposure and on good hand hygiene practices when discharged from the hospital.

RSV can cause severe lower respiratory tract infection (LRTI) in LTRs. Although most infections resolve with or without therapy, fatal cases have been reported, as have long-term declines in pulmonary function.^{59,192,372,606} The diagnosis can be made from nasal washings by rapid antigen-detection kits, standard viral culture, or more rapid shell vial culture methods, although PCR-based assays, which provide sensitive detection of a broad range of viral pathogens, are now considered the preferred method.³⁵⁵ Risk factors for poor outcome in immunocompromised patients include neutropenia, lymphopenia, age younger than 1 year, underlying lung disease, and augmented immunosuppression. High mortality rates in hematopoietic stem cell transplant recipients have led to prevention and treatment strategies that can serve as models for care in SOTRs,^{144,194,611} although they are not without controversy.^{59,195} A recent survey of centers providing adult lung transplantation documented differences in therapy. While all transplant centers treated LRTI with ribavirin, some used inhaled, some oral, with different dosing regimens, with or without steroids and/or IVIG. Some centers treated upper RTI (URTI) to prevent LRTI.⁴⁸ This heterogeneity demonstrates the need for further studies to define optimal treatment. Supportive care and reduction in immunosuppression remain the mainstay of therapy. For children with URTI and risk factors, or LRTI, aerosolized ribavirin should be considered. In addition, because outcomes, even in treated hematopoietic stem cell transplant recipients, are poor with ribavirin alone, some experts suggest combination therapy with RSV IVIG or monoclonal antibody (palivizumab) for immunocompromised patients with significant infections.^{59,82} Increasingly published reports using oral ribavirin, which is considerably easier and less expensive to use, suggest successful treatment.^{324,332,357,449} Several investigational drugs undergoing clinical trials show promise, including oral ALS-008176, a nucleoside analogue that inhibits viral polymerase, and ALN-RSV01, an intranasal small interfering RNA targeting RSV replication.^{145,146,202,632} Effective prophylaxis with palivizumab and RSV IVIG has been achieved in young infants with lung disease.^{214,378} Care must be taken when extrapolating to other patient populations, given the unexpected poor

outcomes of some infants with complex congenital heart disease who were administered RSV IVIG⁵¹⁸ but not pavilzumab.¹⁶² Some experts would consider the use of immunoprophylaxis in young infants undergoing organ transplantation during the RSV season.³⁵⁵

hMPV was described in healthy young children in 2001.⁵⁷⁴ It has signs and symptoms similar to those of RSV, and almost universal infection probably occurs by 5 years of age.⁶¹⁴ The impact of hMPV on immunocompromised patients is as yet uncharacterized, in part because diagnostic tests have only recently become widely available. The virus can be cultured, but reverse transcriptase PCR appears to be the test of choice and is available as part of a PCR respiratory viral panel in most centers.¹⁸ Studies on adult LTRs demonstrate that hMPV respiratory viral illnesses are common, often with coinfections and associated with graft dysfunction/acute rejection, but less likely than RSV infections to be associated with chronic graft rejection and BOS.^{192,241,308,604} There is no established therapy for hMPV infections outside of supportive care and treatment of co-pathogens, although ribavirin and IVIG are sometimes utilized.^{241,355}

PIV (types 1 to 4) is isolated frequently as a cause of URTIs and croup in normal children.²¹ PIV can cause severe lower tract infection in immunocompromised patients, including respiratory failure in LTRs, most notably caused by serotype 3.^{26,586,588,607} Although rarely fatal in adults, persistent declines in pulmonary function and acute allograft rejection are important consequences of PIV infection.^{372,586,607} A retrospective study on PIV in pediatric SOTRs (after liver, small bowel, lung, heart, kidney transplants) found significant age-related morbidity and mortality.²⁶ Although 44% of all patients with PIV infection had URTI, only 11% of children younger than 1 year had limited disease. A 16% mortality rate was associated with PIV, and predictors of mortality included age younger than 6 months, infection occurring less than 3 months after transplantation, and augmented immunosuppression. Infection in these children occurred in the context of community outbreaks. The diagnosis can be made by PCR assays and antigen detection; culture isolation can take weeks. Respiratory secretions obtained from nasal washings or BAL fluid can be used.⁵⁹ No proven therapy for PIV in LTRs is available. Intravenous and aerosolized ribavirin has been used in immunocompromised hosts, but without randomized controlled data or clear evidence of efficacy.^{59,355,372} A novel sialidase fusion protein, DAS181, which removes viral receptors from respiratory epithelial cells, shows therapeutic promise and is currently in clinical trials for PIV in immunocompromised patients.^{216,496,594}

Transplant recipients are at risk for acquiring community-acquired infection during the yearly influenza A and B epidemics, as well as nosocomial infection from visitors, hospital workers, and other transplant recipients as a result of infections occurring in the inpatient setting.^{183,352,484,587} Seasonal influenza infection is relatively rare in SOTRs—4.2% of adult LTRs over the course of a 10-year period and 2.6% of pediatric SOTRs over a similar period^{26,59}—but LTRs appear to be at a uniquely high risk for acquiring infection. In the adult study, the incidence was 41.8 cases per 1000 person-years for adult LTR versus 2.8 and 4.3 per 1000 person-years in liver and kidney transplant recipients, respectively.⁵⁸⁹ These authors speculate that optimal protection from influenza infection afforded by serum and secretory antibodies in the respiratory tract are altered in LTRs, thereby leading to higher attack rates. In addition, risk for disease and complications are high for pediatric transplant recipients in particular.³⁵⁵ Previous data suggested that upper respiratory tract symptoms were the most common presentation of pediatric SOTRs with influenza, although 3 of 13 patients (23%) died.²⁶ In these children, corticosteroid bolus and OKT3 therapy given within a week of diagnosis of infection were associated with mortality. Transplant recipients may be at increased risk for acquiring secondary bacterial infections and nonpulmonary complications such as hepatitis, myocarditis, and aseptic meningitis.^{59,589} Influenza was the causative agent in 8.9% of 101 respiratory viral illnesses documented in a series of pediatric LTRs observed between 1998 and 2007.³³⁴

Although we have an incomplete picture of the current epidemiology of influenza infections in pediatric LTRs, the H1N1 epidemic of 2009–10 has added to our understanding of its impact. Risk factors for hospitalization and severe disease included age younger than 5 years and immunosuppression.⁶²⁴ Two studies on adult LTRs suggest the majority of

patients did well, but with a wide range of clinical impact from upper respiratory tract symptoms, association with progression to BOS, mechanical ventilation, and mortality (0%, 21%).^{175,415} In a retrospective series of SOTRs (adults and children) with H1N1 infection, children were more likely to have fever, rhinorrhea, sore throat, and headache and less likely to have chest radiographic evidence of lower tract disease.³⁰² Of note, almost 50% of all patients had gastrointestinal complaints. In the pediatric cohort, mortality was 0% versus 7% in adults, with similar rates of admission (66%, 73%) and intensive care unit care (12%, 17.5%). Children were more likely to receive antiviral therapy within 48 hours.

Infection with the influenza virus is unique among respiratory virus infections in that both vaccine and chemoprophylactic strategies are available. Unfortunately immunosuppressed patients may not respond well to influenza vaccine, and, if disease is not recognized promptly, the effectiveness of therapy for established disease may not be optimal. Studies on the immunogenicity of influenza vaccine in pediatric SOTRs are more encouraging than in adult reports, which have documented poor response, especially when associated with mycophenolate mofetil or sirolimus.^{81,227} In pediatric renal transplant recipients, response was similar to that of normal controls, without evidence of rejection,^{157,181} although in pediatric heart transplant recipients protective antibody responses were not achieved until three doses of vaccine were administered.⁵ Preliminary studies using high-dose (60 µg) versus standard-dose (15 µg) trivalent inactivated influenza vaccine suggest no increase in toxicity or graft dysfunction and improved immunogenicity.¹⁹³ No conclusive evidence documents a link between immunization and graft dysfunction with the intramuscular trivalent inactivated influenza vaccines, which have been used routinely for decades.²⁹⁹ The current recommendation is that influenza vaccine be administered yearly to all SOTRs older than 6 months of age and 3 to 6 months after transplantation and to those awaiting transplantation, as well as to household contacts and caretakers.^{2,81,299} During the 2009 H1N1 pandemic, recommendations for immunization were reduced to 1 month after transplant, with the acknowledgment that only partial protection was likely.³⁰³ Children younger than 9 years of age receiving influenza vaccine for the first time should have two doses 4 weeks apart. The use of live attenuated influenza vaccine and intradermal and adjuvant vaccines is not recommended. Oseltamivir chemoprophylaxis can be administered to patients who have not been vaccinated or who have not had sufficient time to respond to vaccination, especially if influenza is circulating in the community or if there is a known exposure. Dosing for young children and infants is now available.^{266,286,303} Other agents approved for prophylaxis of influenza A in children older than 1 year include amantadine and rimantadine (M2 inhibitors), although resistance of influenza A is high and they are not active against influenza B strains.⁵⁸⁷

The diagnosis of influenza should be made by real-time PCR or other nucleic acid–based detection whenever possible. Multiplex PCR assays for respiratory viruses are now routinely available at most centers.³⁰³ See Chapter 178 for additional information on laboratory diagnosis. Most experts would recommend empirical therapy with antiviral agents in an LTR with suspected (community epidemic with compatible symptoms) or proven influenza, regardless of duration of symptoms (e.g., >48 hours).^{59,355} During the 2009–10 H1N1 pandemic, early therapy was associated with improved outcome (decreased hospitalization, intensive care unit, mortality) in high-risk patients as well as normal hosts.^{302,624} The choice of agent depends on the type of virus (A or B) and information about resistance. The neuraminidase inhibitors oseltamivir (oral) and zanamivir (inhaled, IV) are currently favored because of their broad spectrum of activity and less reported resistance.^{355,587} Oseltamivir-resistant H1N1 retained susceptibility to zanamivir.³⁰³ In addition, higher/double doses and prolonged therapy may be necessary because the viral burden and length of shedding are increased in transplant recipients and children. Optimal length of therapy is not known, but the minimum is 5 days; consideration for continuation of therapy until PCR testing is negative must be countered by the concern for emergence of viral resistance. Two intravenous antiviral agents, peramivir and zanamivir, are available, as well as combination therapies undergoing investigation.³⁰³ Choice of antiviral therapy should be made after consultation with the CDC and public health officials about circulating virus strains and resistance patterns.

With improved management of herpesvirus infections and better diagnostic techniques, the impact of adenoviral infections in transplant recipients is increasingly recognized. Adenoviral infections in SOTRs follow the epidemiology of infection in the general population, such that infections are more common in young pediatric than adult transplant recipients, who may remain naïve to many of the 52 recognized serotypes.^{135,171,383,425} Other risk factors for infection include exposure to lytic antibodies, high levels of maintenance immunosuppression, and adenovirus serologic mismatch. Establishment of latency in lymphoid tissue has been documented, and numerous immune evasion genes have been identified.¹⁷¹ Adenoviral infections have multiple putative sources, including the donor organ, reactivation from latency in host tissues, and infection acquired from the community or nosocomially.^{88,290,374,383,460}

Infections in LTR may be asymptomatic, lead to recognizable syndromes of the respiratory and/or gastrointestinal tracts, or cause disseminated disease, defined as involvement in two or more organs. Often disease is most pronounced in the allograft (e.g., pneumonitis, hepatitis, enteritis, hemorrhagic cystitis).¹⁷¹ Cases of acute, disseminated, and fatal disease have been described in cardiothoracic transplant recipients. In LTRs, infections occur in the early posttransplant period and often cause disease in the graft in the form of necrotizing pneumonia.^{75,425} Adenoviral infection has been associated with graft dysfunction, BOS, retransplantation, and death.⁷⁵

Available diagnostic methods for the detection of adenovirus include culture, direct identification of antigens, and serology, as well as histologic examination of tissues for the presence of adenoviral inclusions and immunohistochemical staining.¹⁰³ Direct identification of adenoviral antigens, usually performed on respiratory specimens, can be achieved by radioimmunoassay, immunofluorescence, or ELISA techniques, which are rapid and specific but less sensitive than culture.

PCR assay has emerged as a powerful tool for detection of adenovirus in body fluids (blood, nasal wash, BAL) and tissues and for serotyping.^{171,246} The virus's ability to establish latency can render interpreting the presence of virus or viral DNA in clinical specimens a challenge.^{185,321} A single determination of the presence of adenovirus by PCR assay in immunocompromised patients may be nonspecific and perhaps misleading and should be correlated with histopathology if available and appropriate clinical syndromes to differentiate between asymptomatic infection and disease. As with other important viruses that establish latency, quantitative viral load patterns appear to be more informative with regard to the pathogenic role of adenovirus in these patient populations. No threshold has been identified to predict progression of infection or outcome. Studies in pediatric hematopoietic stem cell transplant recipients (HSCTR) support the use of blood PCR surveillance as a method to identify patients at risk for disseminated disease.^{108,171,328,597} Although routine surveillance is not recommended for LTRs, its use for early detection and monitoring in certain high-risk patients may be advocated.

The optimal therapy for adenovirus infection has not been determined. Supportive care and reduction of immunosuppression are the mainstays of therapy.^{171,620} The role of immune recovery should not be underestimated, of which adenovirus-specific cytotoxic T cells are particularly critical.^{97,229} Cidofovir (CDV), an acyclic nucleoside phosphonate, inhibits viral DNA polymerase with activity against all serotypes. It may be beneficial in severely ill patients with disseminated disease and rising viral loads.^{90,238,318,337,596,628} Use of this agent may be associated with significant renal toxicity,^{228,318,463} and use of modified dosing regimens has been investigated with some success.^{90,238,404,596} CMX001 (brincidofovir) is an oral lipid ester prodrug of CDV with broad-spectrum antiviral activity that achieves very high intracellular antiviral activity and improved toxicity profile. It has been used for therapy for adenoviral infection in immunocompromised patients, mostly HSCTR, and appears promising.^{171,172,620} Strategies involving adoptive immunotherapy, such as infusion of adenovirus-specific cytotoxic lymphocytes that has been investigated in adenoviral infections in HSCTR and other immunodeficient patients,^{163,317,406} may also be feasible, with proof of concept for cytotoxic lymphocyte therapy published for SOTRs and EBV infections.^{74,223,500}

Although a detailed discussion is beyond the scope of this chapter, the link between respiratory viruses, BOS, and chronic allograft dysfunction should be addressed briefly. BOS is a progressive condition without

good treatment options and is the greatest impediment to long-term survival for LTRs. It affects upward of 50% of patients alive 5 years after transplantation and is the leading cause of death in adult and pediatric LTRs 1 year after transplantation.^{570,599} Although the exact mechanisms are still being determined, the final common pathway is epithelial injury and intraluminal proliferation of fibroblasts leading to airflow obstruction.^{258,282,565,585} Activation of innate immune pathways (e.g., Toll-like receptors) in response to pathogen-associated molecular patterns (PAMPs) and more recently recognized endogenous damage-associated molecular patterns (DAMPs),⁵⁶⁶ as well as stimulation of T cells and release of cytokines and chemokines by viruses, are leading candidates for the initiation of these pathways. Not surprisingly, genetic polymorphisms in related genes such as Toll-like receptors, cytokines, mannose-binding lectin, matrix metalloproteinase 7, and others may further help to explain the variability in development in BOS and in the future may allow for risk stratification and personalized therapy.²⁷⁵ Many studies have linked viral infections, such as those caused by CMV, adenovirus, RSV, PIV, and others, often working in concert, to the development of BOS.^{161,301,432,586,588} The exact role of these agents has yet to be proved, although it is biologically plausible.²⁵⁸ Reduction of BOS syndrome remains an incentive for the continued development of preventive strategies against these viral infections.

Donor-Derived and Zoonotic Infections: Rabies, West Nile Virus, Lymphocytic Choriomeningitis Virus, and *Bordetella*

Although most donor-derived infections are expected and CMV, HBV, and the risk to the recipient can be mitigated, the isolation of unusual pathogens often is a sign of an unexpected exposure.^{41,264,489} This statement is epitomized by reports of SOTRs with uncommon zoonotic infections. In the case of donor-derived rabies, lymphocytic choriomeningitis virus, HIV, HCV, Chagas, and West Nile virus infections, multiple cases were traced to a donor or donors with retrospectively assessed exposures and risk factors.^{164,231,265,267,322,543} West Nile virus in SOTRs also has been community acquired,^{287,304} and cases of infection with *Bordetella bronchiseptica* in transplant recipients have been traced to sick pet dogs.^{47,107} These cases are humbling in multiple respects. Many of these infections have no established therapy and, as expected, are associated with increased morbidity and mortality in SOTRs.^{142,164,287,304,413} Therefore prevention is of utmost importance. These cases advise us to counsel our posttransplant recipients and families on avoidance of potentially infectious exposures, such as travel, sick pets, and arthropod vectors of diseases.^{294,300,413} Undeniably they remind us of the almost limitless pathogens that may befall SOTRs, including those not yet described. These cases have newly informed the policies for reporting suspected donor-transmitted conditions and opened a new dialogue on how screening procedures of organ and blood donors are conducted.^{148,164,169,245,264,283} To ensure an optimal balance of patient safety and organ utilization, new guidelines are in place to more accurately define donors with "increased risk for disease transmission."⁵⁰⁶ A rigorous three-pronged approach can mitigate risk of donor-derived infections: risk stratification based on donor medical, behavior, and social history; physical exam/assessment of donor's body (deceased or living) and of the organ itself; and, finally, laboratory screening, including serology, culture, and nucleic acid amplification testing (NAT).²⁶⁴ Going forward, an increased understanding of the epidemiology and risk of donor disease transmission is needed.

Opportunistic Infections in Liver and Intestinal Transplantation

72

Michael D. Green • Marian G. Michaels

Liver transplantation has been established as an effective treatment for children with end-stage liver disease for more than 30 years. Improving surgical techniques and the availability of new and more potent immunosuppressive regimens have led to enhanced survival rates, with 3-year survival rates approaching or exceeding 84%.⁶⁰ In response to these excellent results, children with end-stage liver disease are routinely referred for liver transplantation, and increasing numbers of pediatric centers routinely perform this procedure. Intestinal transplantation, performed as an isolated procedure or in combination with the liver or other organs, has also gained expanded acceptance as a treatment for children with refractory intestinal failure, with steadily improving survival rates over time.¹⁰² This is particularly true for those children who experience progressive liver failure due to hyperalimentation-induced

liver disease. Although this newer procedure has been routinely performed at a relatively limited number of centers, an increasing number of transplant programs are beginning to offer intestinal transplantation.

Infectious complications have been a significant cause of morbidity and mortality in children undergoing liver transplantation since this procedure gained its initial acceptance in the 1980s. However, improvements in the treatment options for and management of immune suppression along with the increasing availability of new antimicrobial agents and diagnostic tools have resulted in reductions in the impact of infectious complications on these children. Intestinal transplantation is associated with many of the same infectious complications seen after liver transplantation, as well as a number of infectious issues that appear to be unique to this procedure. Although development of increasingly

effective treatment strategies for infectious complications is of great benefit to the children undergoing these procedures, emphasis has increasingly shifted to the development of strategies aimed at the prevention of infectious complications in children undergoing abdominal transplantation. A general overview of the problem of infections after liver and intestinal transplantation in children is presented in this chapter.

PREDISPOSING FACTORS

Liver and intestinal transplantation are associated with a set of technical and medical conditions that predispose to a unique set of infectious complications. The abdomen is a common site of infection in patients undergoing both of these procedures.^{24,67} This is almost certainly due to the occurrence of local ischemic injury and bleeding, as well as potential soilage with contaminated material.⁴⁹ Additional factors predisposing to infection can be divided into those that exist before a transplant and those secondary to intraoperative and posttransplant activities.

Pretransplant Factors

The underlying illnesses leading to transplantation may be associated with intrinsic risk factors for infection. Some disorders may have required palliative surgery, which increases the technical difficulty of the transplant and may be associated with an enhanced risk for developing post-transplant infections.²⁰ For example, children undergoing liver transplantation for biliary atresia may have previously undergone a Kasai procedure (choledochojunostomy), which may predispose to recurrent episodes of bacterial cholangitis before transplantation, increasing the likelihood of colonization with multidrug-resistant (MDR) bacteria that can cause infection after transplantation. Similarly children undergoing liver transplantation for cystic fibrosis may have an increased risk for developing invasive aspergillosis if they were colonized with this pathogen before transplantation. Complications of end-stage liver disease (as part of a primary liver disease or as a consequence of hyperalimentation in patients with intestinal insufficiency) may also predispose to infection after a transplant. A history of one or more episodes of spontaneous bacterial peritonitis before transplantation in patients with ascites has been associated with an increased rate of bacterial infections after liver transplantation¹¹⁴ and could occur in patients with liver disease associated with intestinal insufficiency. Finally children awaiting intestinal transplantation experience frequent episodes of gastrointestinal-associated bloodstream infections. Recurrent exposure to antimicrobial agents to treat these episodes of bacteremia increases the likelihood of colonization and disease with MDR bacterial and fungal pathogens after transplantation. Risks for bacterial translocation after intestinal transplantation with resultant bloodstream infection include the presence of a colon graft,¹⁸ hospitalization before transplantation, and treatment with mycophenolate mofetil (MMF).⁶⁷

Age, another important pretransplant factor, is a major determinant of susceptibility to certain pathogens, severity of expression of infection, and immune maturation.¹ Young children undergoing abdominal transplantation may experience moderate to severe infection with certain viral (e.g., respiratory syncytial virus [RSV]) or bacterial (coagulase-negative staphylococci) pathogens compared with more mild illness experienced by adult recipients infected with these pathogens. In contrast, certain pathogens, such as *Cryptococcus neoformans*, uncommonly manifest infection before young adulthood.¹¹⁷ Age is also an important factor governing clinical expression of infection with cytomegalovirus (CMV) and Epstein-Barr virus (EBV). When transplants are performed in young patients, there is a high likelihood that they will be seronegative for CMV and EBV and therefore susceptible to primary infections, which are more severe than infections due to reactivation.^{9,50,92}

Donor-related issues represent another set of pretransplant factors. Transplant recipients are at risk for acquiring infections that may be active or latent within the donor at the time of organ harvesting. The most common examples of donor-associated infections are CMV and EBV.^{8,10,16,92} Infections caused by CMV and EBV have been more severe after intestinal transplant compared with other organs. This may be because the intestine is an organ rich in lymphoid tissue, which may result in bringing a larger viral load of viruses from the donor compared

with other graft types. Similarly adenovirus has been isolated more commonly from pediatric recipients of intestinal transplants compared with other organs, which may also be related to donor transmission in the accompanying lymphoid tissue.^{29,74,87} In contrast to CMV and EBV, for which donor-derived transmission is expected, increasing attention has focused on the unexpected transmission of other pathogens such as human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV). Although the systematic use of donor screening has led to a decreased frequency of unexpected transmission of HIV, HBV, and HCV,^{3,25,57} evidence demonstrates donor-associated transmission of West Nile virus and rabies, as well as a number of other uncommonly transmitted pathogens.^{56–58,106} Because organs from a single donor often go to disparate sites, it is important for the recipient center to report back to the United Network for Organ Sharing (UNOS) any unusual infections that might possibly have come from the donor.

Intraoperative Factors

Operative factors unique to liver transplantation may predispose to infectious complications. For example, liver transplant recipients undergoing Roux-en-Y choledochoduodenostomy experience more infectious episodes than do those who undergo a choledochocolocholestomy with T-tube drainage.^{62,94} However, only the former option is usually performed in children undergoing liver transplantation because of the small size of their bile ducts. For combined liver-intestinal transplantation, evolution to en bloc replacement of the liver and intestine avoids the need for additional biliary anastomosis and minimizes the risk for infection related to biliary complications. Prolonged operative time (>12 hours) during the initial transplant has been associated with an increased risk for infection after transplant^{34,62} and is likely a surrogate marker for the technical difficulty of the surgery. Intraoperative events, such as contamination of the operative field, also predispose to postoperative infections. Finally the inability to close the abdomen after the transplantation due to size discrepancy or intraoperative complications appears to increase the risk for postoperative infections.

Posttransplant Factors

Technical problems, immunosuppression, presence of indwelling canulas, and nosocomial exposures are major postoperative risk factors for infectious complications. Thrombosis of the hepatic artery is the most serious technical problem after liver transplantation and predisposes to areas of necrotic liver and development of hepatic abscesses and bacteremia.^{93,94} Bile duct strictures, developing as a sequelae of thrombosed hepatic artery and ischemia or due to technical difficulties, may predispose to cholangitis.⁹⁴ Retransplantation represents a high risk for intraabdominal infection after intestinal transplantation.⁶⁷

Immunosuppression is the critical postoperative factor predisposing to infection in all transplant recipients. Immunosuppressive regimens have evolved in an attempt to achieve more specific control of rejection with the least impairment of immunity. Thus this evolution is aimed not only at improved control of rejection but also at decreased morbidity and mortality from infections. The use of cyclosporine-based regimens resulted in a decreased incidence of infections in renal and cardiac transplant recipients.^{24,51,83} The introduction of tacrolimus has allowed many patients to be managed without corticosteroids.^{42,113} Although reported rates of infection have been similar in liver transplant recipients treated with tacrolimus compared with those receiving cyclosporine, an apparent decrease in morbidity and mortality, especially from viral pathogens, was noted with tacrolimus.⁴² In contrast to these results, some centers reported an increased rate of EBV-associated posttransplant lymphoproliferative disease (PTLD) in patients receiving tacrolimus.¹⁹ However, data from the University of Pittsburgh suggest that the short- and long-term incidence of EBV-associated PTLD appears to be similar in pediatric liver transplant recipients treated with either cyclosporine or tacrolimus.¹² More recently, induction immunotherapy has been used in combination with corticosteroid-free or corticosteroid-sparing immunosuppressive regimens, and newer agents also are being explored. Potential infectious risks will need to be assessed for these and other evolving immunosuppressive regimens.

Children undergoing intestinal transplantation require an increased baseline level of immunosuppression compared with patients undergoing

most other solid-organ transplant procedures.⁹² With this increased level of immunosuppression has come an increased risk for development of infection. In an effort to overcome this, a number of alternative immunosuppressive strategies have been explored. Looking at one such alternative strategy, Loinaz and colleagues found an increased risk for bacterial infections with both MMF and daclizumab after intestinal transplantation.⁶⁷ Another alternative approach evaluated the use of alemtuzumab induction in pediatric intestinal transplant recipients, and this was associated with a marked increased incidence of EBV-associated PTLT in one study⁹⁸ but not another.⁵⁹

The treatment of rejection with additional or higher doses of immunosuppressant agents increases the risk for invasive and potentially fatal infection. Of particular concern is the use of antilymphocyte preparations, which are often indispensable in the management of corticosteroid-resistant rejection.^{8,34,62}

The prolonged use of indwelling cannulas at any site is an important cause of infection throughout the postoperative course. The presence of central venous catheters is a cause of bacteremia after transplantation. This is particularly important for children undergoing intestinal transplantation, where maintenance of long-term central venous access has been required for prolonged periods of time after transplantation.³¹ The development of urinary tract infections and bacterial pneumonia are associated with the use of urethral catheters and prolonged nasotracheal or endotracheal intubation, respectively.^{34,62}

Nosocomial exposures constitute the final group of postoperative risk factors in the hospital setting. Transplant recipients, especially children, may be exposed to many common viral pathogens (e.g., rotavirus, RSV, or influenza) while hospitalized. The presence of resistant bacteria in the hospital increases the risk for nosocomial transmission and disease. Attention to infection control policies aimed at local epidemiology of circulating infections is paramount. Finally the presence in the hospital of heavy areas of contamination with pathogenic fungi, such as *Aspergillus*, may increase the risk for invasive fungal disease in these patients. The rate of fungal colonization increases during times of hospital construction. Infection control policies aimed at local epidemiology of circulating infections is paramount.

TIMING OF INFECTIONS

The time of onset of infection with various pathogens after transplantation tends to be predictable. The majority of clinically important infections occur within the first 180 days after transplantation,^{40,62} although infections continue to occur quite frequently beyond this time after intestinal transplantation.⁵⁹ The timing of infections can be divided into three intervals: early (0 to 30 days after transplantation), intermediate (30 to 180 days after transplantation), and late (>180 days after transplantation). In addition, some infections may occur throughout the postoperative course. These divisions should be viewed with flexibility because they may be modified by prophylaxis strategies and are somewhat less applicable to recipients of intestinal transplantation. Despite this, they remain useful, giving a general approach to a patient with fever after transplantation, and can be used as a guide to differential diagnosis. An overview of the infectious complications occurring during each of these time periods is provided in Tables 72.1 to 72.3 and is summarized in the following sections.

Early Infections (0 to 30 Days)

Early infections (Table 72.1) tend to be associated with preexisting conditions and surgical manipulation. In general, they are caused by either bacteria or yeast. Bacterial infections are particularly common after intestinal transplantation, being reported in up to 90% of recipients.^{67,110} As many as half of these early infectious complications may develop in the first 2 weeks after abdominal transplantation.⁷ Cholangitis or spontaneous bacterial peritonitis presenting at or near the time of liver transplantation may lead to intraabdominal infection after the transplant. Technical difficulties (e.g., thrombosis of the hepatic artery or portal vein and biliary strictures) predispose to early bacterial infections. Likewise development of bile leaks and bowel perforations are associated with polymicrobial intraabdominal infections, primarily consisting of enteric bacteria and *Candida* spp., in the first month after

TABLE 72.1 Differential Diagnosis of Infectious Complications During the Early Period (0–30 Days) After Pediatric Liver and Intestinal Transplantation

Clinical Syndrome	Associated Pathogens
Wound infection:	
Superficial	<i>Staphylococcus aureus</i> Enterococci
Deep	Enterobacteriaceae Enterococci <i>Staphylococcus aureus</i> <i>Candida</i> spp.
Intraabdominal infection:	
Peritonitis	Enterobacteriaceae
Intraabdominal abscess	Enterococci
Intrahepatic abscess (isolated liver and liver-intestine transplants) ± bacteremia	<i>Candida</i> spp.
Bloodstream infection, associated with:	
Central venous catheters	Coagulase-negative staphylococci Enterobacteriaceae Enterococci <i>S. aureus</i> <i>Candida</i> spp.
Hepatic artery thrombosis (isolated liver transplant only)	Enterobacteriaceae Enterococci <i>Candida</i> spp.
Intestinal rejection (intestine only)	Enterobacteriaceae Enterococci <i>Candida</i> spp.
Bacterial cholangitis (isolated liver transplant only)	Enterobacteriaceae Enterococci <i>Candida</i> spp.
Urinary tract infection	Enterobacteriaceae Enterococci <i>Candida</i> spp.
Ventilator-associated pneumonia	Enterobacteriaceae Enterococci <i>S. aureus</i>
Nosocomial acquisition of common community pathogens	Respiratory syncytial virus Parainfluenza virus Influenza virus Human metapneumovirus Rotavirus Norovirus
Noninfectious etiologies	Rejection Drug fever

transplantation.³⁵ Early bacteremia is exceptionally common in intestinal transplant recipients and is usually associated with the presence of central venous catheters.³¹ Likewise early bacteremia with gram-negative pathogens in these children has been associated with intestinal rejection.^{31,37} Reexploration of the abdomen is associated with increased rates of fungal infection.⁶² Finally herpes simplex infection can also reactivate and cause early symptomatic disease,⁶² although this is uncommon in children.

Intermediate Period (31 to 180 Days)

The intermediate period (Table 72.2) is the typical time of onset of infections associated with nonbacterial donor-associated transmission (either organ or blood products), reactivated viruses, and opportunistic infections. CMV peaks in incidence during this time.^{8,62} However, the use of prophylaxis against CMV can modify the time of presentation so that the occurrence of disease from these organisms may be after 180 days. The intermediate period is also when many patients begin to present with EBV disease (including PTLT)^{11,50} and *Pneumocystis jiroveci*

TABLE 72.2 Differential Diagnosis of Infectious Complications During the Intermediate Period (31–180 Days) After Pediatric Liver and Intestinal Transplantation

Clinical Syndrome	Associated Pathogens
Viral syndrome (fever, leukopenia, thrombocytopenia \pm atypical lymphocytosis)	CMV EBV
Hepatitis	CMV EBV Adenovirus Hepatitis B Hepatitis C
Enteritis	CMV EBV Rotavirus Adenovirus <i>Clostridium difficile</i>
PTLD	EBV
Bacterial cholangitis ^a	Enterobacteriaceae Enterococci <i>Candida</i> spp.
Pneumonia	<i>Streptococcus pneumoniae</i> CMV Adenovirus RSV Parainfluenza virus Influenza virus Human metapneumovirus <i>Pneumocystis jiroveci</i> <i>Aspergillus fumigatus</i>
Bacteremia ^b	Enterobacteriaceae <i>Enterococcus</i> Coagulase-negative staphylococci (with central venous catheter) <i>Candida</i> spp.
Adenopathy	EBV/PTLD
Pulmonary nodules	EBV/PTLD <i>Aspergillus fumigatus</i>

CMV, Cytomegalovirus; EBV, Epstein-Barr virus; PTLD, posttransplant lymphoproliferative disease.

^aTypically only seen in isolated liver transplant recipients and usually associated with the presence of technical complication (e.g., biliary stricture).

^bSeen in intestinal transplant recipients in association with presence of central venous catheters, intestinal rejection, or PTLD involving intestine.

pneumonia.⁶² Finally bacteremia continues to be a frequent occurrence in pediatric intestinal transplant recipients, with as many as 50% of all bloodstream infections occurring in this population being identified in this time period.³¹

Late Infections (Greater Than 180 Days)

Late infections (Table 72.3) after abdominal transplantation are less well characterized than other periods because patients have usually been discharged from the transplant center to their respective homes, which often are quite far away. This makes the accurate accumulation of data on these late infections difficult. Nonetheless problems such as recurrent episodes of bacterial cholangitis in liver transplant recipients (typically associated with underlying problems of the biliary tree) and bacteremia associated with ongoing requirement for a central venous catheter, intestinal graft rejection, and/or PTLD in intestinal transplant recipients, continue to occur in this time period.^{31,67} In addition, children who are at high risk for CMV infection and have been kept on prolonged or recurrent courses of prophylaxis may develop late-onset CMV infection in the late period.¹⁴

TABLE 72.3 Differential Diagnosis of Infectious Complications During the Late Period (>180 Days) After Pediatric Liver and Intestinal Transplantation

Clinical Syndrome	Associated Pathogens
Bacterial cholangitis ^a	Enterobacteriaceae Enterococci <i>Candida</i> spp.

EBV, Epstein-Barr virus; PTLD, posttransplant lymphoproliferative disease.

^aUsually associated with the presence of technical complication (e.g., biliary stricture).

^bSeen in intestinal transplant recipients in association with presence of central venous catheters, intestinal rejection, or PTLD involving intestine.

^cRespiratory syncytial virus, parainfluenza virus, influenza virus A and B, human metapneumovirus, adenovirus, rhinovirus, and enterovirus.

Infections Occurring Throughout the Postoperative Course

Iatrogenic factors are an important cause of bacterial and fungal infections at all times but predominate in the early transplant period. Central venous lines are maintained for a variable time; the risk for infection persists for the entire period that the catheter remains in place. This is a particularly important problem for recipients of intestinal transplants who frequently require central line access for prolonged periods of time. Similarly the presence of urethral catheters and endotracheal tubes increases the risk for infections whenever they are in use.

Nosocomial acquisition of community viruses, such as RSV, rotavirus, and influenza A or B can occur at any time after transplant. These viruses spread easily in hospital environments from personnel or other hospitalized patients to transplant recipients. It is therefore important to modify diagnostic considerations according to local epidemiologic considerations.

BACTERIAL AND FUNGAL INFECTIONS

Bacterial and fungal pathogens are important causes of morbidity and occasional mortality in children undergoing liver and/or intestinal transplantation. With the exception of infections related to the use of indwelling catheters, sites of bacterial infection tend to occur at or near the transplanted organ. Accordingly the intraabdominal space is an important site of infection after any of the abdominal transplant procedures. Adding to the complexity of the management of bacterial infections in children undergoing abdominal transplantation is the fact that recovery of MDR bacteria is increasingly common. Outbreaks of colonization and disease due to vancomycin-resistant *Enterococcus faecium*, extended-spectrum β -lactamase (ESBL)-producing *Klebsiella pneumoniae*, and carbapenem-resistant Enterobacteriaceae have been reported among pediatric liver and intestinal transplant recipients.^{17,36,107}

These MDR bacteria have been transmitted from patient to patient, prompting the need for close attention to and strict compliance with infection control procedures. In some cases, effective antimicrobial agents may be unavailable to treat these complications. Knowledge of results of previous cultures and antimicrobial resistance patterns locally as well as from the home institution of the patient are critical components in choosing initial empirical antibiotic therapy for these patients to maximize their outcomes.

Liver Transplantation

Bacterial and fungal infections are a common early problem after liver transplantation.^{52,116} Rates for bacterial infection of 40% to 70% have been reported from multiple series.^{51,76,110} A 2008 review of the SPLIT registry for children undergoing liver transplantation between 1995

and 2006 found that around 33% of pediatric liver recipients experienced a bacterial infection, with the vast majority of these presenting in the first 30 days after transplant.⁹⁶ Similar rates have been reported following living donor liver transplantation in children. Bacteremia often occurs in association with intraabdominal infection or with use of central venous catheters, but it can occur without an obvious source. Enteric gram-negative organisms account for more than one-half of episodes.⁸² Bacterial infections involving the abdomen or surgical wound are common in most series. Infectious complications of the transplanted liver also occur. The most important complication is hepatic abscess associated with hepatic artery or portal vein thrombosis, which can be accompanied by persistent bacteremia. However, the introduction of frequent surveillance Doppler studies early after transplant to monitor for development of thrombosis, coupled with the use of operative thrombectomy and thrombolysis, have markedly diminished the development of hepatic abscesses in this population.

Ascending cholangitis is relatively common after liver transplantation accounting for 7% of infections in the SPLIT series and usually associated with biliary abnormalities.⁹⁶ This diagnosis typically is made on clinical grounds in a patient with fever and biochemical evidence of biliary inflammation. Enteric gram-negative bacteria and enterococcal species predominate. However, this clinical picture can be identical to that of acute graft rejection; liver biopsy should be performed to differentiate these processes. A cholangiogram is performed to assess the status of the biliary tract for patients with proven cholangitis.

Historically as many as 40% of children undergoing liver transplantation developed a fungal infection during the first year following this procedure, with *Candida* spp. being the most common fungal pathogen and infection usually being associated with an intraabdominal focus or indwelling catheter.¹¹⁶ Infections due to *Candida* spp. have been most commonly recognized in the first month after transplantation, with candidal peritonitis most likely presenting in the first 2 weeks after liver transplantation in association with a bile leak or bowel perforation. The recovery of *Candida* from a Jackson-Pratt drain in the early postoperative period may be the first indication of either of these two technical complications and may occur before the onset of clinical symptoms of intraabdominal infection.³⁵ Accordingly recovery of *Candida*, alone or in combination with enteric bacteria, should prompt initiation of antimicrobial therapy and an aggressive evaluation for the presence of these complications. However, rates of invasive candidiasis have markedly declined, as demonstrated by a recent study of pediatric liver transplant recipients at two different centers that found that only 2.5% of 397 children developed invasive candidiasis in the first month following transplantation²² as compared to a rate of 21% documented in an older study evaluating invasive candidiasis during the first month posttransplant.⁴⁰ Candidemia accounted for 80% of episodes of invasive candidiasis in the recent series with the only identified risk factor associated with the development of candidal infection being ICU admission in the 2 weeks prior to transplant. Historically additional risk factors for fungal infection have included prolonged duration of intubation after transplant, hepatic artery thrombosis, volume of blood transfused, and exposure to corticosteroids within the 3 months before the transplant. Early initiation of antifungal treatment is particularly important, given an attributable mortality rate of up to 33% for candidal infections in pediatric liver transplant recipients in older literature.³⁵ The availability of fluconazole and echinocandin antifungal agents (e.g., caspofungin, micafungin, and anidulafungin) increases the number of therapeutic options for the treatment of candidal infections. However, acquired or inherent resistance to the azoles is an increasing concern, as are drug-drug interactions between azoles with both cyclosporine and tacrolimus and echinocandins with cyclosporine.

Episodes of invasive aspergillosis among pediatric liver transplant recipients are uncommon but can be fatal⁴³; infections due to other invasive molds are rarely seen. However, children undergoing liver transplantation for cystic fibrosis (CF) are at particular risk for developing infection due to *Aspergillus* and other fungi seen in children with CF lung disease.⁵⁴ Early disseminated aspergillosis in children with CF undergoing liver transplantation at Children's Hospital of Pittsburgh of UPMC (CHP) was observed in the early era of transplantation, prompting the use of perioperative antifungal prophylaxis in liver

recipients with CF and a history of recovery of *Aspergillus* before transplant. Because data defining the precise duration of prophylaxis necessary to protect against this complication are not available, prophylactic treatment has ranged from 1 month of intravenous amphotericin to prolonged use of an oral azole agent (e.g., itraconazole or voriconazole). The availability of newer antifungal agents, including the advanced-generation azoles (voriconazole and posaconazole) as well as the echinocandins, has increased the number and complexity of therapeutic options for treatment of aspergillosis in children undergoing liver transplantation.⁴⁵ A summary of a suggested approach to the diagnosis and management of fungal infections after liver transplantation in children is provided in Table 72.4.

Intestinal Transplantation

Although increasing, the numbers of children having undergone intestinal transplantation remain relatively small. Many have received combined liver and intestine or multivisceral transplants. Bacterial infection occurs frequently in these patients.^{37,97} One series reported that as many as 92% of children undergoing intestinal transplantation experienced an average of 2.9 episodes of bacterial infection per patient.⁶⁷ More than 80% of these patients experienced their first bacterial infection during the first 2 months after transplant. Bacteremia, which can be explained in part by disruption of the mucosal barrier associated with harvest injury or intestinal allograft rejection, is a common finding,^{37,97} with one center reporting that 69% of pediatric intestinal transplant recipients experienced at least one episode of bloodstream infection.³¹ Coagulase-negative staphylococci, enterococci, and gram-negative enteric bacilli account for most episodes. As noted earlier, antibiotic resistance is commonly seen in recovered pathogens. In the CHP experience, episodes of gut-associated bacteremia frequently secondarily infect central venous catheters, producing persistent positive cultures even after resolution of clinical symptoms. Accordingly treatment strategies aimed at preserving the catheter (e.g., antibiotic lock therapy) may need to be used in combination with systemic antibiotics to accomplish a sustained clinical cure.⁷⁶

Intraabdominal and wound infections also are seen commonly in this population, occurring in more than one-third of patients, and are typically detected during the first month after transplantation. Gram-negative enteric pathogens, which frequently demonstrate multiple-antibiotic resistance as well as enterococci (often exhibiting vancomycin resistance) are the most common organisms associated with these complications. Recurrent laparotomies have been identified as a risk factor for intraabdominal infection. One unique aspect of intestinal transplantation is the potential inability to achieve abdominal wall closure. Although failure to close the abdominal wall is an obvious risk for the development of intraabdominal infection, the use of abdominal mesh as part of efforts to resolve difficult abdominal wall closures has also been associated with the development of superficial and deep wound infection.²³

Another important site of infection is the intestine itself. *Clostridium difficile* enteritis can present with fever, abdominal pain, and diarrhea that can easily be mistaken for graft rejection or viral infection due to CMV, EBV, and adenovirus. Accordingly the diagnosis of *C. difficile* enteritis must be considered in any child in whom fever and changes in stool output are noted. In one small series, *C. difficile* enteritis was diagnosed in nearly 10% of children undergoing intestinal transplantation.¹²¹ The frequent exposure to antibiotics and prolonged hospital stays that children undergoing intestinal transplantation experience are major risk factors for the development of this complication. Standard treatment with oral metronidazole is the recommended first-line therapy. However, use of oral vancomycin (including prolonged tapered courses) or alternate therapies such as fidaxomicin might be necessary for patients who experience relapse or recurrent episodes after primary treatment.

Invasive candidiasis and candidemia occur relatively frequently after intestinal transplantation in children, with one center reporting an incidence of approximately 23% in a series of 98 pediatric intestinal transplant recipients.³² Candidemia accounted for 50% of the episodes of infection in this series, whereas nearly 40% involved the intraabdominal space. Although the majority of episodes of candidemia infection occur

^aCommon: >5%; uncommon 1–5%; rare <1%.

^bTopical amphotericin B for bladder wash for noninvasive candiduria; ultrasonography of kidneys recommended to confirm absence of invasive disease.

^cAzole use must be accompanied by close follow-up of levels of cyclosporine or tacrolimus. In general, tacrolimus dosing should be cut in half when using a standard dose of fluconazole.

^dDose varies according to specific agent.

^eFluconazole is alternative first-line drug for invasive disease if the species is known to be sensitive to fluconazole and the patient is clinically stable. Dosage is 6 to 12 mg/kg per day based on severity of infection.

^fFlucytosine should not be used alone but is synergistic when used in conjunction with amphotericin B. Dosage is 100 to 150 mg/kg per day divided every 6 hours.

^gRadiographic staging includes computed tomography of head, chest, and abdomen.

^hItraconazole can be used long term for patients who have been treated for invasive *Aspergillus* but in general is not recommended as first-line therapy.

ⁱItraconazole absorption can be erratic. Accordingly, monitoring of itraconazole levels is recommended. Itraconazole is dosed at 3 to 5 mg/kg per day as a single dose. Dosing adjustment based on monitoring of levels is recommended. Adjustment of cyclosporine or tacrolimus dosing should be individualized.

^jThe use of either of the approved echinocandins (caspofungin, micafungin, or anidulafungin) may be an appropriate alternative for treatment of invasive candidiasis, candidemia, and aspergillosis. Dose adjustments may be necessary in the presence of impaired liver function. Monitoring of tacrolimus levels are indicated because these agents may decrease tacrolimus levels.

^kVoriconazole levels should be checked for patients treated with oral therapy.

CSF, Cerebrospinal fluid.

in the first 3 to 6 months after transplant, later episodes may occur. Intraabdominal infection with *Candida* frequently present as part of a polymicrobial infection related to technical problems occurring during the initial transplant surgery or subsequent laparotomies. Specific risk factors associated with invasive candidiasis and candidemia include ongoing requirement for total parenteral nutrition and antibiotic treatment in the 7 days before diagnosis.³²

Invasive mycoses due to fungal pathogens other than *Candida* are rarely observed. A recent report on fungal infections from the University of Nebraska identified four cases of invasive aspergillosis in 98 children undergoing intestinal transplantation,²⁸ whereas our experience at CHP has identified rare infections with *Aspergillus*, *Alternaria*, and *Scedosporium* in this population. In general, these children have been on high levels of immune suppression or have other complications such as PTLT, and outcome of these infections has been poor. Guidelines for the diagnosis and management of fungal infection in children undergoing intestinal transplantation are provided in Table 72.4.

VIRAL INFECTIONS

Viral pathogens, especially herpesviruses, are a major source of morbidity and mortality after solid-organ transplantation. Patterns of disease associated with individual viral pathogens generally are similar among all transplant recipients. However, frequency, mode of presentation, and relative severity can differ according to the type of organ transplanted and the serologic status of the recipient.

Cytomegalovirus

CMV continues to be the most common and one of the most important viral pathogens after organ transplantation in children. CMV infection can be asymptomatic or symptomatic and may be due to primary infection (either from the donor graft or blood products), reactivation of latent infection, or infection with a different CMV strain in a previously seropositive child. Prior to the use of prophylaxis, the incidence of symptomatic CMV infection was reported to be as high as 40% in pediatric liver transplant recipients.⁸ Use of ganciclovir prophylaxis or

viral monitoring to inform preemptive treatment has resulted in a decreased rate and severity of CMV disease. Intestinal transplantation was introduced after the availability of ganciclovir and therefore has been able to take advantage of using ganciclovir both as prophylaxis and treatment. Despite this, it is clear that CMV disease can be very severe after intestinal transplantation and may have a high rate of recurrence.¹⁰ More recent reports identify decreased incidence and severity of CMV disease in this population, although, compared to CMV after other organ transplants, these patients continued to experience high recurrence rates of CMV infection, more severe disease, and high rates of resistance.^{30,70,81,112} Primary CMV infection, typically acquired from the donor organ (or passenger donor leukocytes that accompany the organ), is associated with the greatest degree of morbidity and mortality.^{32,112} Accordingly CMV-seronegative recipients of organs from CMV-seropositive donors are considered at high risk for developing CMV disease. Reactivation of or infection with a new strain of CMV tends to result in milder illness after liver transplantation but can still be severe after intestinal transplantation.⁹ CMV disease appears more likely to develop in CMV-seropositive recipients of CMV-seropositive donors than in seropositive recipients of seronegative donors. Patients treated with unusually high doses of immunosuppressants, especially antilymphocyte antibody preparations, experience an increased rate of CMV disease regardless of previous immunity.^{8,62}

Symptomatic CMV disease classically presented between 1 and 3 months after transplantation. It is important to note that the use of prophylactic or preemptive monitoring regimens may delay onset of CMV disease.³⁰ When present, a characteristic constellation of fever (which may be high-grade, prolonged, and hectic) and hematologic abnormalities (including leukopenia, atypical lymphocytosis, and thrombocytopenia) is frequently seen. This “CMV syndrome” occurs in 25% to 50% of patients with symptomatic CMV infection. Invasive CMV disease is manifest by visceral organ involvement; common sites include the gastrointestinal tract, liver, and lungs. CMV hepatitis appears to be the most common site among liver transplant recipients, whereas CMV enteritis is a frequent finding among intestinal transplant recipients. CMV chorioretinitis is rare in organ transplant recipients.

Diagnosis of CMV disease may be confirmed by detecting the presence of CMV DNA or pp65 antigen in the blood of a patient with a compatible clinical syndrome.¹¹¹ The pp65 antigenemia assay is less frequently used in recent years as nucleic acid test (NAT) assays have become more widely available. Clinicians must be aware that results of viral cultures of the urine, bronchoalveolar lavage specimens, or even a positive blood test for CMV by NAT or pp65 antigen, are difficult to interpret in previously infected patients because CMV is identified in these sites in the absence of clinical disease. Serial evaluation of quantitative determinations of the pp65 antigen or CMV DNA may add to specificity, but histologic examination of involved organs to confirm the presence of CMV remains the gold standard when the diagnosis of invasive CMV is being entertained.^{61,91}

Antiviral agents with activity against CMV (e.g., ganciclovir, foscarnet, and cidofovir) have improved the survival of transplant recipients with CMV disease. Fatal disseminated CMV disease occurred in 19% of infected children⁸ and 5% of infected adults undergoing liver transplantation in the era before ganciclovir was introduced.⁹⁹ For clinical CMV disease, ganciclovir therapy is given in conjunction with reduction of immunosuppression unless evidence of rejection is present.⁶¹ Clinical response usually occurs 5 to 7 days after initiation of therapy. Baseline immunosuppression levels are typically restored at the time of initial clinical response or on recognition of rejection. Data support the use of serial monitoring of CMV load in the peripheral blood as a guide to initiation of and duration of CMV therapy.^{61,91} Valganciclovir was equally efficacious in treating adult kidney transplant recipients with CMV disease but not those who had undergone liver transplantation.⁵ Controlled studies in children are lacking, but many centers use valganciclovir in children once they are discharged from the hospital. The role of CMV hyperimmune globulin in combination with ganciclovir in the treatment of CMV disease is controversial, although some evidence for improved outcome has been reported in the treatment of CMV pneumonia in adult liver transplant recipients.⁶¹ Finally because of the relatively high rates of nephrotoxicity associated with their use, foscarnet

or cidofovir should be restricted to patients with apparent or proven resistance to ganciclovir, which should be suspected in patients who either fail to clinically improve or have persistent or rising CMV viral loads after 2 weeks of ganciclovir therapy.^{61,91}

Historically approximately 25% of patients treated with ganciclovir for an initial episode of symptomatic CMV will develop one or more episodes of recurrent CMV disease,¹⁰⁸ although rates of recurrent disease may have fallen in the presence of longer initial treatment and the use of secondary prophylaxis.⁶¹ When present, recurrences are observed about 1 month after the initial infectious episode and may be associated with invasive disease. More commonly, however, these recurrent episodes tend to be milder than the initial episode. Factors identified with an increased risk for developing recurrent CMV disease include being a CMV-seronegative recipient of a CMV-seropositive donor, having disseminated CMV disease, and having a history of multiple treatment courses for rejection and persistent elevations of the CMV load at the end of therapy.⁶¹ Although current guidelines recommend continuing antiviral therapy until the CMV viral load becomes negative, further research is needed on duration.^{61,91} A summary of our suggested approach to the diagnosis and management of CMV infection is provided in Table 72.5.

Epstein-Barr Virus

EBV infection, including EBV-associated PTLD, is an important cause of morbidity and mortality after liver transplantation and intestinal transplantation.^{2,11,50,120} This is particularly true among children undergoing intestinal transplantation, who experience higher rates of EBV-related disease than any of the other organ transplant recipients.⁸⁵

Symptomatic EBV infection in general and PTLD in particular most commonly occur among transplant recipients experiencing primary EBV infection, particularly those who receive organs from seropositive donors. Accordingly children undergoing transplantation are disproportionately affected by EBV compared with their adult counterparts.³⁹ As many as 80% of children who are EBV seronegative before liver transplantation will develop a primary EBV infection after this procedure.^{101,105} Although primary infection occurs in the vast majority of seronegative patients, clinical disease develops in less than one-third of these children.^{101,105} In one study, 4% of children undergoing solid-organ transplantation and 10% of children with primary EBV infection developed PTLD between 1 month and 5 years after transplant⁵⁰; 75% of cases occurred during the first postoperative year in patients undergoing cyclosporine-based immune suppression. Historically cumulative occurrence rates reached as high as 12% to 20% by 7 to 12 years after pediatric liver transplantation.^{68,80} Current rates of PTLD in this cohort appear lower, with an incidence of 4.4% at 5 years after liver transplant for recipients who were EBV seronegative prior to the procedure, likely owing to improvements in immune suppression and the use of preventive monitoring strategies.⁶⁰

Pediatric recipients of intestinal transplantation appear to behave differently than children undergoing other types of organ transplantation in that the rate of EBV disease, including PTLD, occurs irrespective of EBV serostatus before transplantation. Rates of EBV disease and PTLD after intestinal transplantation as high as 30% to 40% were reported during the initial experiences with intestinal transplantation. More recently, these rates have declined to approximately 11%,⁷⁰ reflecting improved immune suppression regimens and EBV-monitoring protocols. However, these rates still remain higher than those seen among other organ recipients.

A wide spectrum of EBV disease is recognized that includes non-specific viral illness, mononucleosis, and PTLD (including lymphoma). Histologic evaluation is important in differentiating among these categories; manifestations can evolve in individual patients. Asymptomatic seroconversion also occurs. Variation in severity and extent of disease is related to the degree of immunosuppression and adequacy of the host immune response. Although EBV disease and PTLD may present as involvement of many different clinical sites, there is a tendency for EBV disease to involve the transplanted organ. Thus EBV hepatitis and PTLD of the liver are observed more commonly among liver transplant recipients. Similarly the intestine is the most frequently observed site of involvement of EBV disease among intestinal transplant recipients.

TABLE 72.5 Overview of Diagnosis and Management of Viral Infections After Liver and Intestinal Transplantation in Children

	CMV	EBV	Respiratory Syncytial Virus	Influenza	Parainfluenza	Adenovirus
Frequency	Common ^a	Common	Uncommon	Uncommon	Uncommon	Liver: uncommon ^b Intestine: common ^a
Diagnostic tests	Culture Quantitative CMV PCR (blood) pp65 antigen Histology	Quantitative EBV PCR (blood) Histology Serology	NP aspirate for antigen detection or PCR	NP aspirate for antigen detection, PCR and/or culture	NP aspirate for culture or PCR	Viral culture or PCR Histology
Treatment:						
Primary	Ganciclovir IV (5 mg/kg bid)	Decrease immune suppression	Supportive care	Supportive care Oseltamivir Zanamivir	Supportive care	Decrease immune suppression
Secondary	Foscarnet ^c Cidofovir ^c	Rituximab Cytosine/prednisone	Aerosolized ribavirin ^d			IV cidofovir
Adjunctive	Decrease immune suppression CMV-IVIG	Ganciclovir IVIG	Palivizumab Decrease immune suppression	Decrease immune suppression	Decrease immune suppression	IVIG ^c
Duration of therapy	Site dependent	Individualized	Individualized	Individualized	Individualized	Individualized
Follow-up	Monitor quantitative CMV PCR or pp65 (treat until negative)	Monitor quantitative EBV PCR Repeat imaging studies if positive at outset	None	None	None	None

^aCommon: frequency approximately >5%.^bUncommon: frequency approximately 1–5%.^cFoscarnet or cidofovir used for CMV infection when ganciclovir resistance is suspected or proved. Experience from HIV-infected patients suggests that a synergistic benefit will be obtained from the combined use of both of these agents when ganciclovir resistance is present.^dSome experts have used oral ribavirin, but definitive data on efficacy are lacking.

CMV, Cytomegalovirus; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; IV, intravenous; IVIG, intravenous immunoglobulin; NP, nasopharyngeal; PCR, polymerase chain reaction;

Of interest, involvement of sites beyond the gastrointestinal tract is uncommon in intestinal transplant recipients.

Onset of viral syndrome, mononucleosis, and PTLT occur primarily within the first year, whereas lymphoma tends to present later. Immunosuppressive regimens based on the use of tacrolimus appear to have affected a shift in the timing of PTLT; only rare cases occur later than 18 months after liver transplant, although late cases are more likely to occur after intestinal transplantation.^{13,120,102} The impact of newer immunosuppressive agents and regimens on EBV disease needs to be constantly reevaluated because unexpectedly high rates of PTLT have occurred with some new regimens.^{44,98}

The diagnosis of EBV-associated PTLT is made on the basis of clinical, laboratory, and histopathologic examination and should be suspected in patients with protracted fever, exudative tonsillitis, lymphadenopathy, organomegaly, leukopenia, or atypical lymphocytosis.^{39,85} Gastrointestinal involvement should be suspected in patients with persistent fever and diarrhea. Accordingly EBV must be considered in the differential diagnosis of rejection among intestinal transplant recipients. Serologic diagnosis is often confounded by the presence of passive antibody acquired at the time of transplantation or during subsequent transfusions. The detection of increased EBV viral load in peripheral blood identified by PCR has gained wide acceptance as an assay to predict risk for or presence of EBV or PTLT.^{39,85} Although extremely sensitive, these assays are limited by both a lack of uniformity across different laboratories⁸⁹ and their lack of specificity; they are often elevated in asymptomatic patients.^{2,39} Accordingly every effort should be made to histologically confirm the diagnosis of EBV or PTLT. Occult sites of PTLT are assessed by computed tomography of chest and abdomen. More recently, increasing interest has focused on the potential role of positron emission tomography (PET) scans as an alternative or supplemental imaging modality in the diagnostic evaluation of patients thought to have EBV disease and/or PTLT.^{2,39} Palpable nodes or lesions

(or both) identified by radiographic surveillance should be sampled. Endoscopic evaluation should be considered in patients with diarrheal illnesses and elevated viral loads.¹⁵ Histologic evaluation for typical features may be augmented through the use of the Epstein-Barr-encoded RNA (EBER) probe.⁹⁰ The use of the EBER probe may be particularly useful in differentiating between the presence of rejection and EBV infection among intestinal transplant recipients.

Management of patients with PTLT is controversial.^{2,39,85} Reduction of immunosuppression is recommended widely. Antiviral agents typically are used,⁴⁷ although their role has not been studied formally. Reduction of immunosuppression, alone or in combination with antiviral agents, results in an approximate 67% cure rate of EBV disease and PTLT. The potential impact of monoclonal antibodies,²⁷ interferon,⁹⁵ and chemotherapy³³ awaits formal clinical trials. Resection of tumor also may be of value for patients with lymphoma. Recent experience has focused on several novel approaches to the management of EBV disease and PTLT. These newer strategies have typically been used for patients who fail to respond to reduction of immune suppression (with or without the use of antiviral agents). Rituximab, an anti-CD20 antibody, has been increasingly used for the treatment of EBV disease. Experience to date suggests that as many as two-thirds of patients who fail initial withdrawal of immunosuppression will respond to a 4-week course of this agent.⁴¹ However, relapse of EBV disease has been observed in 20% to 25% of treated patients 6 to 8 months after completion of therapy at the time the rituximab is no longer present in the body. An alternate chemotherapy-based approach for patients who fail to respond to initial reduction or withdrawal of immunosuppression has also been proposed.⁴⁶ This strategy, which uses modified doses of cyclophosphamide and prednisone, has also achieved success in approximately two-thirds of treated patients. Unfortunately, as with rituximab, relapse of PTLT has been seen in 22% of treated patients, and outright treatment failures have occurred in patients presenting with fulminant disease. Definitive

studies comparing these two second-line therapies are needed to define the best option for those children who fail to respond to initial therapeutic modification of immunosuppression. A summary of our suggested approach and management of EBV/PTLD is provided in [Table 72.5](#).

Other Herpesviruses

Other herpesviruses can also be hazardous after transplantation. Herpes simplex virus (HSV) can reactivate early after surgery or after augmentation of immunosuppression. Prophylaxis with acyclovir (or ganciclovir) has been beneficial in these situations. A summary of the suggested approach to the diagnosis and management of HSV is provided in [Table 72.5](#). Primary varicella infection (chickenpox) in transplant recipients can lead to disseminated, fatal disease⁷³ and should be treated early and aggressively with intravenous acyclovir. Some centers have used valacyclovir rather than intravenous medication, but further studies are needed. Reactivation disease as shingles is more commonly seen in adults and can be prevented with antiviral prophylaxis early in the transplant period. Valacyclovir can be used for treatment if shingles is mild, but if severe or disseminated, then intravenous acyclovir use is prudent.

Interest has also focused on determining what role, if any, human herpesvirus-6 (HHV-6) and 7 (HHV-7) may play in causing disease in organ transplant recipients in general and abdominal transplant recipients in particular. Several groups of investigators have identified a potential interaction between the development of HHV-6 and HHV-7 and CMV infection in organ transplant recipients.^{55,75} Reactivation of HHV-6 infection after liver transplantation has been associated with the development of an increased CMV viral load in the peripheral blood as well as a greater likelihood of developing symptomatic CMV disease.⁵⁵ In addition, it has been suggested that some or all of the symptoms typically associated with the CMV syndrome (e.g., fever, leukopenia) in patients with proven CMV infection may be attributable in part to HHV-6 or HHV-7. Studies in children have suggested that infection due to HHV-6 alone is a relatively common cause of unexplained fever in pediatric liver transplant recipients.^{118,119} Interest also exists in the role, if any, that human herpesvirus-8 (HHV-8) may have in causing infection and disease in organ transplant recipients. This is particularly true for recipients who come from countries with moderate to high rates of HHV-8 prevalence such as Africa, the Middle East, and the Caribbean.⁷⁹ The full spectrum of disease of these more recently recognized herpesviruses and their potential therapies remain to be determined.

Adenovirus

Adenovirus has been reported to be the third most important virus affecting pediatric liver transplant recipients, occurring in 10% of one series of 484 children undergoing liver transplantation under cyclosporine-based immunosuppression.⁷⁸ Symptomatic disease (ranging from self-limited fever, gastroenteritis, or cystitis to devastating illness with necrotizing hepatitis or pneumonia) occurred in more than 60% of infected patients. Infection was most commonly diagnosed within the first 3 months after transplantation.⁷⁷ The frequency of invasive adenovirus infection after pediatric liver transplantation appears to have decreased markedly with the use of tacrolimus-based immunosuppression.⁴² In the tacrolimus era, McLaughlin and colleagues found that only 4.2% of pediatric liver recipients experienced adenovirus disease.⁷⁴ This is in contrast to a significantly higher incidence of 20.8% of adenovirus infection in pediatric intestinal transplant recipients at the same institution. A high rate of adenovirus infection after pediatric intestinal transplantation was also reported by Florescu and colleagues, who noted that 39% of their cohort was infected, with 60% of infected patients recognized as having adenovirus-attributed disease.²⁹ Finally Pinchoff and colleagues found adenovirus in all 14 of their pediatric intestinal transplant recipients.⁸⁷ However, these exceptionally high rates might be attributable to the fact that viral cultures and PCRs were performed as part of routine screening of graft biopsies, and not all of the patients were symptomatic. When symptomatic, high stool output, alone or in the presence of fever, was the most common sign found.

It is difficult to presumptively diagnose infection due to adenovirus in pediatric abdominal transplant recipients because fever, hepatitis,

and pneumonia may be caused by a variety of other pathogens, and high stool output after intestinal transplantation is nonspecific and can also occur with rejection. The presence of high-grade fevers and symptoms suggestive of adenovirus infection should prompt serial cultures for viruses (including adenovirus) or PCR investigation and evaluation of graft biopsies. Unexplained elevations in hepatocellular enzymes suggestive of hepatitis should warrant consideration of a liver biopsy. Similarly an increase in stool output, with or without fever, should prompt endoscopic evaluation of the intestinal allograft. Histologic examination for the presence of adenoviral inclusions as well as the use of immunohistochemical stains of biopsies specimens from either site should be undertaken to help confirm this diagnosis.

Definitive evidence evaluating potential treatments for adenoviral disease is not available at this time. The most important component of therapy is supportive care along with a decrease in immunosuppression. The role of antiviral agents is unproved,^{6,77} but increasing data support the use of cidofovir in bone marrow⁶⁶ or solid-organ transplant recipients.^{26,77} Current available guidelines support consideration of use of this agent for patients with proven disease.²⁶ Ongoing studies are investigating the potential role of brincidofovir (a lipid ester of cidofovir), which is currently in trial in bone marrow transplant recipients.²⁶ This drug, which is orally bioavailable, has been associated with less nephrotoxicity and may actually be more potent than the parent compound. Finally a single case report also raised the possible role of intravenous immunoglobulin as treatment for adenovirus infection.²¹ A summary of a suggested approach to the diagnosis and management of adenovirus infection is provided in [Table 72.5](#).

Common Community-Acquired Viruses

Although the course of illness has been poorly documented, most children who undergo liver and intestinal transplantation experience the usual respiratory viruses and gastrointestinal illness without significant problems. However, infections due to influenza virus, parainfluenza virus, or RSV lead to more severe disease in young children, especially if infection occurs soon after transplant and/or during periods of maximal immunosuppression.^{4,57,88} Likewise transplant recipients may have prolonged viral shedding even after resolution of symptoms. A summary of suggested strategies for the diagnosis and management of these community-acquired viruses can be found in [Table 72.5](#).

Other Viruses

Other viruses, including both donor-associated viral infections (e.g., hepatitis B and hepatitis C virus) as well as community-acquired viral pathogens (e.g., rotavirus, norovirus, arboviruses) are relatively uncommon causes of clinically significant infection or disease after abdominal transplantation. Although this may be explained in part by the paucity of data describing infectious complications late after transplant, severe infection owing to these agents appears uncommon. For those patients for whom infection due to these pathogens is recognized, consultation with the primary transplant center is strongly recommended. Suggested approaches to the diagnosis and management of each of these viral pathogens are provided in [Table 72.5](#).

OPPORTUNISTIC INFECTIONS

P. jiroveci is a well-documented cause of pneumonia in immunocompromised patients, including liver and intestinal transplant recipients. Prophylactic trimethoprim-sulfamethoxazole is safe, inexpensive, and effective.^{53,54} The use of this strategy has eliminated *P. jiroveci* pneumonia in these patients at CHP, with rare breakthroughs occurring in patients who discontinued prophylaxis. Alternative prophylactic regimens for the sulfa-allergic patient include aerosolized pentamidine (for patients >5 years of age)⁶⁴ atovaquone or dapsone.⁶⁹

Tuberculosis (TB) is a particular concern in immunosuppressed hosts, including recipients of liver and intestinal transplantation. The incidence of TB after liver transplantation in Europe and the United States has been reported to range from 0.9% to 2.3%, with most reported cases in adults.^{100,115} In contrast, up to 15% of organ transplant recipients in areas of high-level endemicity may develop TB.¹⁰⁰ However, development of TB after pediatric liver transplantation is uncommon, with

less than 20 cases reported.^{71,100,115} To date, no cases have been reported among recipients of intestinal transplantation. Development of TB among solid-organ transplant recipients is associated with mortality rates ranging from 25% to 40%, with additional morbidity and mortality associated with development of rejection in patients receiving anti-TB therapy.^{100,115} Diagnosis of TB in transplant recipients is complicated by the fact that extrapulmonary disease occurs frequently and purified protein derivative (PPD) testing is likely to be unreliable after transplant. Management of TB in liver transplant recipients is difficult both because of the side effects of anti-TB agents and their potential interactions with immunosuppressive agents.^{100,115} Limited published experience in pediatric liver transplant recipients suggests that the majority of infections due to *Mycobacterium tuberculosis* are most likely due to a primary infection often associated with family contacts who have positive skin tests.¹¹⁵ In contrast, experience with adult transplant recipients suggests that development of TB is more likely due to reactivation of latent TB.^{48,100,115} Although only limited published information is available describing TB in these patients, transplant recipients known to have a positive PPD or who come from an area endemic for TB appear to be at increased risk for symptomatic reactivation after transplantation.^{48,115} Similar data are not available for recipients of intestinal transplantation. Additional factors predisposing to the development of TB after transplantation include severe hepatic failure at the time of transplant, aggressive antirejection therapy, and/or concurrent HIV infection.^{48,109} Experience among adult renal transplant recipients suggests that although the risk appears greatest in patients who received inadequate or no prior TB therapy,⁶⁵ it can also occur in patients who received appropriate anti-TB therapy in the pretransplant period.⁶⁵ Although TB has only rarely been encountered among pediatric liver transplant recipients,¹¹⁵ and not among intestinal recipients, screening for TB by history and a PPD test or interferon- γ release assay (IGRA), along with review of a chest radiograph for lesions consistent with healed TB, is highly recommended. However, the use of IGRA assays for even immune-competent children younger than 5 years of age is not recommended at this time. Patients with a positive TB history and/or a positive screening test (either PPD or IGRA) result should receive isoniazid for 6 to 12 months after transplant, although some experts recommend continuing this agent indefinitely while patients remain on immunosuppression. Attempts at a more definitive diagnosis are indicated for patients from endemic areas with a negative PPD result but suggestive chest radiograph. Careful evaluation for evidence of side effects, particularly hepatotoxicity, is recommended, and isoniazid is discontinued if unacceptable toxicity is identified.

Additional potential opportunistic infections include cryptococcosis, coccidioidomycosis, and histoplasmosis, although the pathogens of these infections have not been frequently reported among pediatric liver or intestinal transplant recipients. Prior infection with these pathogens is common in geographic areas where they are endemic. Because patients often travel to transplant centers distant to their homes, it is imperative that transplant physicians be aware of the local environmental risks for each patient. Experience with coccidioidomycosis in transplant recipients suggests that a minimum of 4 months of antifungal therapy, such as fluconazole, should be given in transplant recipients with this history.⁸¹ Similarities between coccidioidomycosis and other fungal pathogens suggest that similar strategies may be necessary for patients with a positive history of prior fungal infection with pathogens known to recur after resolution of primary infection.

MANAGEMENT

Pretransplant Evaluation

A pretransplant evaluation is helpful in the management of infectious complications in liver and intestinal transplant recipients. A complete history and physical examination should be performed with particular attention paid to previous infections, immunizations, and drug allergies. Attention should be paid to a history of infection with MDR bacteria, which may provide guidance for future empirical treatment that may be required after transplantation. An intermediate-strength tuberculin skin test or an IGRA for children older than 5 years of age should be performed on all patients.

The CHP pretransplant protocol includes obtaining serology for CMV; EBV; varicella; herpes simplex virus; hepatitis A, B (surface antibody, surface antigen, and core antibody), and C; and HIV for all candidates. In addition, serology to measles, mumps, and rubella is obtained to ensure that the patients have a measurable antibody response to prior immunizations. Serologic tests on the donor should include HIV, hepatitis B and C, CMV, and EBV. Donors positive for HIV should be excluded, with the rare exception of approved research protocols in the United States as prescribed under the HOPE Act. The use of organs from donors who test positive for hepatitis B or C virus would typically be contraindicated except in the circumstance in which the recipient is also positive for hepatitis B or C, respectively. Knowledge of donor and recipient status for these viruses allows one to anticipate infection, identifying patients who might benefit from prophylactic regimens and guiding in the diagnostic evaluation of fever.

Prophylactic Regimens

Prophylactic regimens vary among transplant centers. These strategies have been divided into perioperative and long-term prophylaxis and often evolve to reflect the infectious complications seen at individual institutions.

Perioperative prophylaxis is used to prevent intraoperative sepsis and wound infection. It is based on individual patient characteristics and expected normal flora. At CHP, piperacillin-tazobactam is used as the standard agent for perioperative prophylaxis. This is modified if the recipient is known to harbor antimicrobial-resistant bacteria. If sepsis is suspected in the donor, antibiotics are chosen to cover those organisms identified from the donor, and treatment is usually extended to a therapeutic course of 10 to 14 days. In the absence of proved or suspected infection in the donor, perioperative prophylaxis is usually limited to the first 48 hours after transplant.

Considerations regarding long-term prophylaxis against infections occurring beyond the perioperative period include the risk and severity of infection as well as the toxicity, cost, and efficacy of a given prophylactic strategy. Nystatin is recommended for all pediatric transplant recipients in an effort to prevent oropharyngeal candidiasis until the patients are on less than 5 mg/day of prednisone. Trimethoprim-sulfamethoxazole is used to prevent *P. jiroveci* pneumonia. Although some centers recommend using trimethoprim-sulfamethoxazole for only the first 6 months after liver transplantation, anecdotal experience with patients presenting with PCP long after transplant and the relative safety of this agent have led us to recommend its use indefinitely after liver and intestinal transplantation in children.

The frequency and severity of CMV infection in transplant recipients prompts consideration of prophylactic strategies; optimizing the target population and timing of interventions requires further study.^{61,91} Current guidelines primarily focus on two approaches to the prevention of CMV: chemoprophylaxis, where all "at risk" recipients receive antiviral therapy for a defined period, and surveillance monitoring of CMV load in blood (most commonly using NAT) in those deemed to be at risk to inform preemptive initiation of antiviral therapy.^{38,61,91} Data on use of monitoring and preemptive therapy after pediatric transplantation remain sparse, although sequential use of shorter courses of prophylaxis followed by monitoring (also called *hybrid method*) has been employed⁶¹ and is currently favored by many pediatric transplant centers.

Whichever CMV prevention strategy is chosen, potential roles exist for intravenous and oral ganciclovir and oral valganciclovir as the antiviral agents for these strategies. Currently CHP protocols use intravenous ganciclovir alone (for varying durations) for liver and low-risk intestinal transplant recipients (recipient CMV positive before transplant or donor and recipient seronegative) and ganciclovir plus intravenously administered immune globulin containing a high titer of antibody against CMV^{103,104} for high-risk (donor CMV positive and recipient CMV negative) intestinal transplant recipients if available. As noted earlier, at CHP, we now include sequential monitoring to inform the need for a secondary course of antiviral therapy after completion of an initial course of antiviral chemoprophylaxis. At present, the use of oral valganciclovir is an alternative to prophylaxis with intravenous ganciclovir for adolescents, although the use of this medication is not

approved for liver transplant recipients because a higher rate of tissue-invasive disease was observed in liver transplant recipients receiving valganciclovir compared with oral ganciclovir in the pivotal trial evaluating this agent.⁸⁶ Nonetheless published guidelines support the use of valganciclovir for adult liver transplant recipients.^{61,91} Pharmacokinetic studies for dosing oral valganciclovir suspension in children after transplantation adjusted for body surface area and renal function suggest that ganciclovir exposures similar to those established as safe and effective in adults can be achieved.

Similar to CMV, there is an interest in the prevention of EBV infections and PTLT. A number of different strategies are used, including immunoprophylaxis, viral load monitoring, and preemptive therapy^{41,72}; the efficacy of these approaches has not been established. The use of viral load monitoring to inform preemptive reductions in immunosuppression appears to be the most promising of these strategies.^{2,63,72} Because reduction of immune suppression is not always possible for intestinal transplant recipients with a rising EBV load, preemptive intravenous ganciclovir and intravenous immune globulin have been used in addition to reduction of immune suppression (where possible) for this cohort of patients. Although prospective comparative data are not available, the use of this strategy appears to have resulted in decreased risk for disease and improved outcome compared with historical controls who were not followed with this strategy.³⁷ The use of anti-CD20 monoclonal therapy has also been used by some centers when decreased immunosuppression is not possible.

CONCLUSION

Infections remain an important problem after liver and intestinal transplantation. Knowledge of the type, timing, and predisposing risk factors for these infectious complications allows for their timely and appropriate diagnosis and management.

Opportunistic Infections in Kidney Transplantation

73

Gail J. Harrison

Renal transplantation is the therapy of choice for end-stage renal disease (ESRD) in children and adolescents.^{37,161,220,261} It is successful in 90% of recipients and allows most children the best opportunities for normal growth and development and an almost normal lifestyle.^{87,165,255} Despite the overall success of renal transplantation, infection remains the major cause of morbidity, graft loss, and mortality in renal transplant recipients.^{62,103,156,248} Effective immunosuppressive regimens have reduced the rates and hospitalizations for graft rejection after renal transplantation, but rates and hospitalizations for bacterial and viral infections seem to be unchanged or increasing.^{65,166,213} Prednisone-free maintenance immunosuppressive combinations with tacrolimus, mycophenolate mofetil, and sirolimus help maintain graft function, but they also may increase the risk for development of infections, including posttransplantation lymphoproliferative disorders (PTLD), papillomaviruses, and invasive fungal diseases.^{122,158}

These infections can be managed successfully if detected early and treated appropriately.¹²² In this chapter a general approach to renal transplant recipients is presented from the perspective of the infectious disease specialist. Specific, detailed information regarding the diagnosis and management of each particular pathogen can be found in the respective chapters in the section of this textbook dedicated to infections with specific microorganisms.

PRETRANSPLANT EVALUATION

The role of the pediatric infectious disease specialist in the care of a renal transplant recipient ideally begins during the pretransplantation period.^{195,197} Before the patient undergoes transplantation, a thorough history and physical examination should be performed, with a focus on evaluation for evidence of an active infection that may require immediate therapy or, rarely, preclude transplantation ([Box 73.1](#)). The history should be comprehensive but focus on the details of any history of previous infections that may reemerge during the posttransplant period, including urinary tract infections (UTIs); mucocutaneous diseases such as herpes simplex virus (HSV) infection; systemic illnesses such as tuberculosis; chronic infections such as those caused by hepatitis B virus (HBV), hepatitis C virus (HCV), or human immunodeficiency virus (HIV); and diarrheal diseases. Infection with HIV previously was regarded as a reason to exclude a potential recipient from undergoing renal transplantation. Patients with primary immune disorders, such as chronic granulomatous disease, may now survive long term but experience end-stage renal failure and require kidney transplantation.³⁵ Successes with highly active antiretroviral therapy have improved long-term survival in HIV-infected pediatric patients, however, and have led clinicians, research scientists, and family members themselves to provide renal transplantation as a treatment for ESRD.^{73,196}

BOX 73.1 Guidelines for Pretransplant Evaluation in Pediatric Kidney Transplant**Candidates****History:**

- Past infectious diseases
- Routine childhood illnesses
- Travel to or birth or residence in areas endemic for fungal or parasitic diseases or Zika virus transmission
- Tuberculosis exposure
- Animal exposure
- Diet preferences and water resources
- Vaccinations
- Reactions or allergies to antimicrobial agents
- Current or past immunosuppression

Physical examination:

- Search for active or latent focus of infection
- Nutritional status

Laboratory and other tests:

- Purified protein derivative
- Chest radiograph
- Urinalysis and urine culture
- Viral serology IgG and or IgM for HSV, CMV, EBV, VZV, human erythrovirus (formerly human parvovirus B19), HAV, HBV, HCV, HIV, BK virus, WNV, ZV, and others depending on the history
- Baseline HSV, CMV and EBV DNA PCR, erythrovirus, HCV, BK virus if seropositive or posttransplant monitoring is anticipated
- Fungal and parasitic testing if travel or exposure history positive; sputum or stool tests as indicated

Anticipatory guidance

- Update vaccines
- Counsel regarding measures to reduce infection risk
- Consider antimicrobial or viral prophylaxis if at risk

CMV, Cytomegalovirus; EBV, Epstein-Barr virus; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; PCR, polymerase chain reaction; VZV, varicella zoster virus; WNV, West Nile virus; ZV, Zika virus.

Renal transplant candidates undergo peritoneal dialysis or hemodialysis, so a history of previous dialysis catheter-associated infections should be documented and any current infection should be treated and eliminated before transplantation is performed. Another focus of the history should include an exposure history for the patient's country of origin or foreign travel, especially to areas endemic for organisms such as *Strongyloides stercoralis*, *Trypanosoma cruzi* (Chagas disease), *Coccidioides immitis*, *Blastomyces dermatitidis*, or *Histoplasma capsulatum*, Zika virus or West Nile virus, and for diseases such as malaria and tuberculosis.^{101,213} Other important exposures include blood product transfusions; exposure to animals or plants; well water as a source of drinking water; and dietary habits, especially consumption of raw or undercooked eggs or meat or unpasteurized dairy products.^{195,197} Patients waiting for transplantation may become colonized with resistant organisms, including methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant *Enterococcus*, gram-negative-multidrug resistant bacteria, fluconazole-resistant or multidrug resistant *Candida* species, and *Clostridium difficile*. In children who are unimmunized, a careful history of routine childhood illnesses, including varicella, measles, mumps, and rubella, should be documented.¹²⁵

The immunization history of the patient should be documented carefully and, if needed or indicated, updated before the patient undergoes transplantation. Ideally children with chronic renal disease should be fully immunized before progression to ESRD for optimal immune response and protection during outbreaks of vaccine-preventable diseases.^{52,162} Vaccinations against tetanus, pertussis, and diphtheria; polysaccharide

vaccines, such as those against pneumococcus and *Haemophilus influenzae* type b; inactivated vaccines against polio and hepatitis A; and recombinant vaccines, such as those for hepatitis B, may be given or updated at any time before transplantation is performed.^{34,241,254} Meningococcal vaccine is indicated routinely now for specific age groups and for special outbreak situations. The live varicella vaccine is recommended for renal transplant candidates who have not had varicella; it should be given at least 2 to 4 weeks before transplantation is performed.²⁷⁵ The measles-mumps-rubella vaccine should be administered even earlier, preferably months before the patient undergoes transplantation. Measles immunity and immunity from other live virus vaccines may wane over time in renal transplant recipients.²¹⁵ In addition, annual influenza vaccine and a tetanus booster every 10 years are recommended for patients who are renal transplant candidates or recipients.

If the child is unable to be fully immunized before undergoing transplantation, the routine immunization schedule for the inactivated vaccines may be reinstituted after immunosuppression is decreased, which usually occurs 6 to 12 months after an uncomplicated transplant procedure.^{34,162,241,254} Live virus vaccines should be avoided in the post-transplant period in most instances. Reports of safe and effective vaccination with varicella vaccine in selected posttransplant patients have been published, however.^{32,43,84,189,190} Close contacts and family members of renal transplant candidates and recipients also should be fully immunized and should receive the annual influenza vaccine.¹¹ Other important points in the pretransplant evaluation history include allergies or reactions to medications, especially antibiotics, and the use of immunosuppressive agents.

Pretransplant laboratory and diagnostic imaging evaluations for most renal transplant candidates should include a chest radiograph, urinalysis, and urine culture for bacteria. Baseline renal and liver function tests also should be performed.

Serologic screening of the transplant recipient's status regarding organisms that may reactivate in the recipient or infect the recipient via the donor organ should be performed; such screening should include tests for HSV; cytomegalovirus (CMV); varicella zoster virus (VZV); Epstein-Barr virus (EBV); human erythrovirus (parvovirus B19); *Treponema pallidum*; *Toxoplasma gondii*; hepatitis A, B, and C viruses; and HIV. Hepatitis E virus has also been shown to infect kidney transplant recipients, but the clinical significance of infection with hepatitis E virus in these patients is not clear.^{226,243} Transplant recipients who are seropositive for HSV or CMV usually receive antiviral prophylaxis during the peritransplant period, whereas recipients seropositive for EBV may undergo posttransplant monitoring. It may be helpful to save an aliquot of the recipient's (and donor's) serum in case unusual circumstances occur, such as infection with West Nile virus (WNV) or Zika virus. In CMV-seropositive transplant candidates, baseline CMV quantitative DNA polymerase chain reaction (PCR) may be useful; and in EBV-seropositive candidates, detection of EBV DNA by quantitative PCR may be helpful to document pretransplant viral load especially if posttransplant virologic monitoring is to be performed.

Evaluation for active or latent tuberculosis infection should also be performed before the transplant. This evaluation should include a history of risk factors, including Bacillus Calmette-Guérin (BCG) vaccination, close contacts, country of origin, and a chest radiograph. In addition, a tuberculin skin test (TST) and interferon- γ release assay (IGR) (QuantiFERON-TB gold, QuantiFERON-TB gold in tube, or T-SPOT.TB) should be performed. Positive IGR assay results predict subsequent development of tuberculosis in adult kidney transplant recipients in whom latent tuberculosis infection cannot be detected by TST.¹³⁰ General reviews of IGR assay results in adults with ESRD and in children also suggest that IGR assays are useful, but caution should be used when interpreting IGR test results in young children, especially when results are discordant with TST.^{45,216} The pretransplant evaluation also is an opportunity for the infectious disease specialist to counsel the patient and family about measures that may reduce the transplant recipient's risk for development of infectious disease complications after the transplant. Patients who have an exposure, or even a suspected exposure, to varicella (chickenpox) or zoster (shingles) should contact their physicians immediately to see whether passive immunoprophylaxis with varicella zoster immunoglobulin or postexposure antiviral therapy with

acyclovir or valacyclovir is indicated. Plans for foreign travel to remote areas also should be discussed with the physician. The transplant recipient should consume only thoroughly cooked meat and seafood and thoroughly washed fresh fruits and vegetables. In addition, drinking water should be pure. Transplant recipients should avoid, if possible, changing cat litter boxes, aquariums, and birdcages and should avoid close contact with people who have viral respiratory tract illnesses. Finally, medical attention should be sought if fever occurs, especially if it is significant or persistent.

POSTTRANSPLANT INFECTIOUS COMPLICATIONS

Infections occurring in the posttransplant period can be grouped into three main time frames: the first month posttransplant (early), 2 to 6 months posttransplant (middle), and 6 months posttransplant and onward (late).^{217,237} Although almost any organism or pathogen can infect a transplant recipient at any time, these time periods provide the clinician with a guide to the organisms and disease processes most commonly encountered (Box 73.2).

Infections Occurring During the Early Posttransplant Period

Infections occurring during the first month after renal transplantation usually are bacterial.²²⁵ Common sites of early infections include the wound, urinary tract, lungs, and indwelling intravascular catheters.²⁰²

Wound Infections

As with any surgical procedure, wound infections may develop in a renal transplant recipient. They occur in approximately 2% of renal transplant recipients and range in severity from a superficial wound infection easily treated with wound care and antimicrobial therapy to deep perinephric abscesses that may be difficult to treat and result in transplant nephrectomy.^{218,225} Wound infections are more likely to occur in patients with technical problems associated with the transplant surgery, including urinary leaks, vesicoureteral reflux, wound hematomas, or lymphoceles.^{171,276} Malnutrition during the pretransplant period may impair wound healing and predispose the patient to development of wound infection.

Open Penrose drains may increase the likelihood of introducing microorganisms into the wound, whereas closed suction drainage, such as with a Jackson-Pratt drain, may reduce this risk. In addition, prompt removal of all drains, usually within 5 days in most uncomplicated cases, and administration of prophylaxis with perioperative antibiotics may decrease the incidence of wound infections; such measures are performed routinely in most renal transplant centers. The regimen usually is aimed at uropathogens and staphylococci. One dose generally is given before the transplant, and the regimen is continued for only 24 hours after the transplant.

The diagnosis of a wound infection should be suspected if erythema, warmth, or discharge is present at the wound site or if an unexplained fever develops. Fluid may drain from the wound persistently, or a fluid collection or abscess may be seen on imaging of the deeper operative sites. The patient will be receiving immunosuppressive agents, however, and the findings may be unusual or the symptoms may be blunted. Any fluid or pus obtained should be stained and cultured for bacterial, mycobacterial, and fungal organisms. Organisms most likely to be identified as causes of wound infection include staphylococci (*Staphylococcus aureus*, especially methicillin-resistant *S. aureus* [MRSA], but also coagulase-negative staphylococci), streptococci, and gram-negative enteric organisms. Unusual, multidrug-resistant, or health care–associated bacterial pathogens and yeast, such as *Candida albicans*, also may cause wound infections after the transplant. In addition, case reports of wound and perinephric fluid collections infected with *Mycoplasma hominis* have been published.²³⁹

Appropriate antimicrobial therapy, initially broad-spectrum and then ultimately tailored to the isolated organism and its susceptibility pattern, should be administered. The duration of appropriate antimicrobial therapy usually is 10 to 14 days or until the wound infection has resolved and the patient has been afebrile for 3 to 5 days. Deep abscesses or unusual organisms may require longer therapy.

BOX 73.2 Timetable for the Occurrence of Common Infections and Usual Pathogens After Kidney Transplantation

Early Period

Wound infections
Urinary tract infection
Bacteremia and sepsis syndrome
Pneumonia
Herpes simplex virus
Hepatitis B virus
Human erythrovirus (parvovirus B19)
West Nile virus
Zika virus?
Seasonal viruses
Drug reactions

Middle Period

Herpesviruses:
Cytomegalovirus
Epstein-Barr virus
Varicella-zoster virus
Herpesvirus types 6, 7, and 8
Polyomaviruses:
JC virus
BK virus
Papillomaviruses
Adenoviruses
Zika virus?
Human erythrovirus (parvovirus B19)
Listeria monocytogenes
Mycobacterium tuberculosis
Atypical mycobacteria
Nocardia
Fungal diseases
Pneumocystis jiroveci
Parasitic diseases

Late Period

Community-acquired respiratory viruses and bacterial pathogens
Urinary tract infection
Streptococcus pneumoniae
Cytomegalovirus
Epstein-Barr virus
Varicella zoster virus
Hepatitis B virus
Hepatitis C virus
Human immunodeficiency virus/acquired immunodeficiency syndrome
Zika virus?

Urinary Tract Infections

UTIs are common developments after renal transplantation and may affect 35% to 79% of renal transplant recipients.^{135,276} Posttransplant UTIs are associated with acute and chronic graft dysfunction and may threaten renal graft survival.^{2,14,39,60,124,176,247} They may occur during the early, middle, or late posttransplant period and should be differentiated as afebrile and febrile.¹²² A UTI that is febrile and occurs during the early or early/middle posttransplant period often is a severe illness complicated by pyelonephritis, urosepsis, metastatic foci of infection, allograft dysfunction, rejection, and relapse.^{178,219} UTIs occurring in the early posttransplant period are associated more often with graft loss than are UTIs that occur later.⁶⁰

The risk for developing an invasive UTI after undergoing renal transplantation seems to be increased in patients with prolonged bladder

catheterization (most catheters can be removed during the first few days after transplant), dysfunctional bladder, ureterovesical disorders with reflux, malnutrition, underlying disorders, renal stones, obstructive uropathy, or a contaminated cadaveric kidney.^{2,195} The inability of the bladder to empty completely or surgical complications, such as hematoma, reflux, or obstruction at the urinary anastomosis, are associated with UTIs. In addition, young infants, especially infants who have vesicoureteral reflux, seem to have a high incidence of complicated UTIs after a transplant procedure.¹⁷⁸ Procedures that address the etiology and correct underlying physiologic and anatomic abnormalities of the bladder and ureters should be performed before transplantation to avoid or lessen development of complications associated with these problems.^{2,14,39,247} Newer surgical techniques allow children with reconstructed bladders to undergo successful renal transplantation with minimal risk for posttransplant development of UTIs.^{171,219}

The organisms most commonly isolated from patients with early onset UTIs include not only the typical gram-negative enteric bacteria but also enterococci, staphylococci, and *Pseudomonas aeruginosa*. Unusual organisms, such as *Streptococcus mitis*, *Serratia marcescens*, and *Corynebacterium urealyticum*, also can be found. Antimicrobial therapy should be tailored to the susceptibility pattern of the organism isolated from the urine. Because 30% of patients experiencing a UTI during the early posttransplant period may have recurrent UTIs, a prolonged 6-week course of antibiotics usually is recommended to reduce the risk for developing a relapsing kidney infection.^{171,219} Antimicrobial prophylaxis may reduce the risk for developing a UTI. Trimethoprim-sulfamethoxazole administered for the first 4 months after renal transplantation is effective in preventing most UTIs and can provide cross-cover prophylaxis against *Pneumocystis jiroveci* pneumonia and other diseases.⁸²

Pneumonia

Pneumonia can occur during the first month after renal transplantation and often is associated with prolonged endotracheal intubation. Gram-positive and gram-negative bacterial pathogens acquired from normal oropharyngeal flora and unusual or health care–associated multidrug-resistant organisms predominate during the early posttransplant period.¹⁹⁷ *Legionella pneumophila* and unusual *Legionella* spp., such as *L. micdadei*, *L. bozemanii*, and *L. dumoffii*, also have caused outbreaks of serious, life-threatening pneumonia in transplant recipients in some centers.^{38,50,134,197} *P. jiroveci* can cause pneumonia in a transplant recipient during the early posttransplant period, but more often it is associated with disease after the first month posttransplant.¹⁰⁴ Rare or unusual pathogens, such as *Rhodococcus equi*, may cause pneumonia in these patients.¹⁴⁷

Patients with pneumonia usually have fever, chills, chest pain, malaise, change in tracheal secretions, cough, dyspnea, tachypnea, change in ventilatory status, rales or rhonchi on auscultation of the lungs, and pulmonary infiltrates evident on a chest radiograph. Pneumonia may be complicated by pleural effusion, empyema, or pulmonary abscess, and death may occur if pneumonia is severe and not diagnosed and treated promptly. Treatment with antibiotics effective against the bacterial pathogens isolated from culture of tracheal aspirates, bronchoalveolar lavage fluid, or lung tissue is appropriate.

Bacteremia, Fungemia, and Sepsis

Bacteremia, fungemia, and sepsis occurring during the early posttransplant period often are associated with indwelling catheters.¹⁹⁶ The urinary tract, surgical wound, or transplanted or native kidney also may be a source.¹⁶⁰

Usual bacterial organisms such as coagulase-negative staphylococci or *S. aureus*, unusual bacterial organisms, and yeasts such as *C. albicans* and other *Candida* spp. may be involved. *Listeria monocytogenes* also may cause primary bacteremia or sepsis at any time after a kidney transplantation has been performed but the greatest risk occurs during the early period. Complications include meningitis, and 10% of these patients may die.^{175,232} Renal transplant recipients also are at increased risk for development of bacteremia with *Salmonella* nontyphoidal species.^{58,116,196}

Complications such as UTI, graft infection, peritonitis, abscesses, and meningitis can occur, and recurrences are common. Therapy for bacteremia, sepsis, or its complications is tailored to the susceptibility

pattern of the organism isolated from the patient's blood. The duration of therapy for uncomplicated bacteremia usually is 10 to 14 days, but a longer course of treatment may be indicated if abscesses occur or an unusual organism is isolated. Removal of the indwelling catheter may be necessary to clear persistent bacteremia, and abscesses and other foci of infection should be drained.

Other Bacterial Diseases

Pediatric renal transplant recipients also seem to be at increased risk for development of antibiotic-associated colitis caused by *Clostridium difficile*.^{47,267} Infection of a lymphocoele with *Pasteurella multocida* has been reported, as has systemic infection with *Bartonella henselae*.^{3,48,64,152,196} A high index of suspicion always must be maintained when evaluating a transplant recipient for infection because the immunosuppression required to maintain the transplanted kidney predisposes the recipient to development of infection with unusual organisms.

Viral Infections

Herpes simplex virus. HSV is the most common virus encountered during the early posttransplant period, although antiviral prophylaxis significantly reduces the risk for development of this infection.^{69,70} It occurs less frequently in pediatric (8%) than in adult renal transplant recipients (30%).^{196,195} Most HSV infections encountered posttransplant are due to reactivation of the recipient's strain; however, primary or recurrent infection acquired from the renal allograft may occur and primary infection from person-to-person transmission has been documented.^{69,196,195,219}

Posttransplant HSV infection may be asymptomatic or associated with disease, most frequently oral ulcers in pediatric patients.⁹⁷ Genital and perianal ulcers may occur in adolescents and adults. Rarely HSV may cause disseminated cutaneous lesions or zosteriform eruptions. HSV esophagitis may be manifested as dysphagia, refusal to eat, irritability, and substernal chest pain, and it may complicate oral HSV disease, especially if the oral mucosa has been traumatized by orogastric or nasogastric tubes. Acute severe hepatitis with hepatic necrosis, often accompanied by hypotension and disseminated intravascular coagulation, also can occur. Tracheobronchitis and pneumonitis may occur as a result of HSV, primarily in patients with pneumonia caused by another pathogen and whose mucosa has been traumatized by endotracheal intubation. It is often severe and life threatening, even with appropriate supportive care and antiviral therapy.¹⁹⁶ Encephalitis also has been reported in renal transplant recipients.⁹²

The diagnosis is made by isolation of HSV in cell culture or detection of viral antigen by immunofluorescence or viral DNA by PCR in the end organ involved. Detection or isolation of HSV in body secretions may represent asymptomatic shedding or disease and should be correlated clinically. If HSV DNA by PCR is detected in blood, viremia is likely present and should be treated. Treatment with acyclovir is recommended for patients with mucocutaneous lesions, viremia, or end-organ disease, and HSV-seropositive transplant recipients should receive acyclovir or valacyclovir prophylaxis during the peritransplant period to prevent development of HSV infection. Most patients receiving ganciclovir, valganciclovir, foscarnet, or cidofovir for CMV prophylaxis also are protected against HSV.

Other viruses. Seasonal viruses, especially winter respiratory viruses such as respiratory syncytial virus, influenza viruses, parainfluenza viruses, and adenoviruses; winter diarrhea viruses, such as rotavirus; and late summer/early fall viruses, such as the enteroviruses, can infect the transplant recipient during the early posttransplant period and cause disease. Such infections may be acquired from the family or the community, or they may occur from health care–associated exposures. Transplant recipients who may not be adequately protected by routine vaccination are at risk for severe influenza and its complications. In 2012, results of a study on oseltamivir prophylaxis with once-daily dosing for 12 weeks during periods of local influenza circulation showed that it was well tolerated and reduced influenza in adult and pediatric kidney and other solid-organ transplant recipients.¹¹⁹ Oseltamivir-resistant influenza A was detected during the study period.¹¹⁹

Renal transplant recipients who are chronically infected with HBV or HCV may experience liver dysfunction during the early transplant

period, but the late posttransplant period, beyond the first year, carries the greatest risk for progression of liver disease to cirrhosis. If a renal transplant recipient acquires HBV soon after undergoing transplantation, acute hepatitis can develop, often with death from liver failure.^{57,196}

Noninfectious Causes of Fever

The most common noninfectious cause of fever in the first posttransplant month is allograft rejection.²¹⁸ Fever often is the first sign of rejection, especially in children, and rejection should be considered if an infectious source of the fever is not identified. Another common noninfectious cause of fever early after transplantation is antilymphocyte antibody therapy (OKT3). The first two or three doses of OKT3 produce a release of cytokines, which cause fever and chills. In most patients, these symptoms resolve after the third dose. Other noninfectious causes of fever during this period include drug reactions and pulmonary emboli.

Infections Occurring During the Middle Posttransplant Period

The cumulative effects of immunosuppression begin to be revealed during the period 2 to 6 months after transplantation. If a significant amount of antirejection therapy is required for multiple episodes of rejection, the effects may be more pronounced. Such immunosuppression allows classic opportunistic pathogens, such as CMV, *P. jiroveci*, *Toxoplasma gondii*, *L. monocytogenes*, *Aspergillus*, and *Nocardia*, to evade immune surveillance and cause disease.^{104,196,266,268} Reactivation of organisms previously infecting the transplant recipient or the donor allograft, including *Mycobacterium tuberculosis*, HBV, HCV, HIV, *H. capsulatum*, and *C. immitis*, also may cause disease. In addition, an occult bacterial focus of infection that was not adequately identified and treated before the transplant may become apparent at this time and cause significant disease.²¹⁸

Herpesviruses

The Herpesviridae (HSV types 1 and 2, CMV, EBV, VZV, and human herpesvirus [HHV] types 6, 7, and 8) share the biologic properties of latency, reactivation, cell association, and oncogenicity, which renders them the most important group of pathogens that affect renal transplant recipients.^{196,227} HSV is more important during the early posttransplant period, whereas the other herpesviruses are important causes of morbidity and mortality during the middle and late posttransplant periods.¹⁰⁵

Cytomegalovirus. CMV may cause primary infection in a CMV-seronegative transplant recipient through a renal allograft or blood product transfusion from a seropositive donor.^{20,56,214} Person-to-person transmission within the family or close community also is possible. Recurrent CMV infection develops in seropositive transplant recipients if the recipient's CMV strain becomes reactivated. The renal allograft from a seropositive donor also can be a source of reinfection to the recipient and produce active CMV infection or disease.^{46,98} CMV infection in renal transplant recipients may cause silent or asymptomatic infection; end-organ diseases such as hepatitis, esophagitis, colitis, encephalitis, vasculitis, and retinitis; and systematic disease with persistent fever and leukopenia with thrombocytopenia. A case report also linked CMV infection with posttransplant occurrence of atypical hemolytic-uremic syndrome that resolved with plasma exchange and ganciclovir antiviral therapy.¹⁸⁸ It has been linked in some studies to allograft dysfunction and nephropathy.

CMV also causes depressed cell-mediated immunity and impaired alveolar macrophage function, rendering the host more vulnerable to other opportunistic infections, such as fungal disease and *P. jiroveci* pneumonia, and it serves as a cofactor for other viruses, such as EBV and HHV-6 and HHV-7.^{129,191,203,250,251} In addition, CMV is associated with acute and chronic rejection and allograft nephropathy and decreased long-term patient survival.^{1,71,140,196,214}

Disease caused by CMV can be documented by isolation of CMV from tissue; detection of CMV DNA by PCR or similar assays in blood, bronchoalveolar fluid, or tissue.^{27,28,199,204,214} Isolation of PCR detection of CMV in urine or saliva documents active infection but has little significance in diagnosis of organ disease; serologic tests may document seroconversion in primary infections but generally should be reserved for pretransplant screening only. Most transplant patients at risk for acquiring CMV disease (i.e., CMV-seropositive recipients [D⁺/R⁺] or

CMV-seronegative recipients [D⁺/R⁻] who received a renal allograft from a seropositive donor) should be monitored by viral surveillance, usually by testing blood weekly for quantitative CMV DNA by PCR.^{26,110}

Detection of significant levels of the virus by quantitative or semi-quantitative assay, or an increase from baseline levels, usually predicts CMV disease.²⁵¹ Reduction of immunosuppression, along with preemptive antiviral therapy, generally is indicated and results in a decrease or resolution of CMV levels detected in blood.^{7,28,51,54,90,95,148} Despite receiving adequate antiviral therapy, some patients have persistently positive low, stable levels of CMV DNA by PCR, however, which should be interpreted within the clinical context.²⁷ In some patients who otherwise appear well, the DNA may be fragmented and nonreplicating, whereas in other patients with persistent symptoms, and rising PCR levels, a strain of CMV resistant to one or more antiviral agents may be the cause.

The antiviral agents currently available for the treatment of CMV disease and preemptive therapy for positive CMV markers include ganciclovir, valganciclovir, foscarnet, and cidofovir.²⁶⁵ For renal transplant patients with moderate to severe CMV-associated disease, 2 to 3 weeks of therapy with intravenous ganciclovir usually is adequate to treat disease; however, patients with CMV retinitis or repeat episodes of rejection may require maintenance therapy, usually with oral valganciclovir.^{117,154,180} Asymptomatic or mild CMV infections may respond to oral valganciclovir administered for 1 to 3 months.^{154,172} Preemptive therapy should be continued throughout the period of immunosuppression in patients who are severely immunosuppressed and at risk for development of CMV disease and recurrence (D⁺/R⁻).^{95,110,155,172} Foscarnet and cidofovir have significant renal toxicity and should be used with caution in renal transplant recipients. Prophylaxis for CMV disease is indicated in high-risk transplant recipients (D⁺/R⁻); options include intravenous CMV immune globulin and oral valganciclovir.^{31,79,90,143,180,223,231,238,260}

Epstein-barr virus. EBV infection in children who have received a renal transplant may be asymptomatic or may be associated with a variety of different syndromes, including a nonspecific viral syndrome, mononucleosis, smooth muscle tumors (leiomyoma), posttransplant PTLD, and lymphoma.^{29,30,66,100,102,112} Infection and disease may occur after primary and recurrent EBV infection, but primary infection is more likely to occur and produce PTLD in younger children than in adults who have received solid-organ transplants.^{39,102} EBV disease may affect 10% of pediatric renal transplant recipients and may develop 1 month to 5 or more years posttransplant, with the risk accumulating every year of posttransplant survival. Recurrence of posttransplant PTLD may also occur years after transplant and may involve unusual sites.^{13,62,233}

Knowledge about posttransplant EBV infection and disease is evolving; as graft survival has improved through more intense immunosuppressive regimens that preserve graft function and other opportunistic infections, such as HSV, CMV, and *P. jiroveci*, being successfully managed, EBV has emerged as a formidable obstacle to successful solid-organ transplantation in children.^{29,61,63,66,100,127,233} The estimated overall risk for development of serious life-threatening EBV-associated illness is at least 4% and increases to 10% in children who experience a primary infection with EBV after undergoing renal transplantation.^{61,112} Other risk factors for PTLD in children who have received solid-organ transplants include receipt of antilymphocyte therapy such as OKT3 for rejection, receipt of tacrolimus, sirolimus, or mycophenolate mofetil rather than cyclosporine for immunosuppression, and CMV or EBV donor/recipient (D⁺/R⁻) mismatch.^{63,121,122}

Nonspecific viral syndromes and mononucleosis occur during the earlier posttransplant period, whereas lymphoma and leiomyoma are more likely to be a manifestation during the late posttransplant period.^{31,66,83,100} Uncomplicated posttransplant mononucleosis is characterized by the self-limited illness of fever, pharyngitis, cervical adenopathy, and splenomegaly. The signs and symptoms of PTLD vary but often include persistent fever, weight loss, and generalized adenopathy.¹¹² The disease frequently is multisystemic and progressive, and involvement of the neck, chest, lungs, gastrointestinal tract, liver, spleen, eyes, and brain, as well as lesions, may be detected by computed tomography of the head, neck, chest, and abdomen.^{4,5,195,228} The renal allograft also may be involved and show dysfunction. Lymphoma may be manifested as solid tumors in the renal allograft, lung, liver, spleen, brain, and soft

tissues.^{83,102} Smooth muscle tumors (leiomyoma) frequently are multicentric and multifocal; they often occur in lung, liver, and spleen but also may occur in unusual locations, including the brain and renal allograft.^{29,100,111}

Laboratory diagnosis of posttransplant, EBV-associated disease is based on detection by PCR of EBV DNA in circulating lymphocytes.^{5,54,75} Quantitative or semiquantitative PCR assays may show increasing or persistently high copies of EBV DNA in the circulating lymphocytes of patients who are at risk for developing PTLD.^{5,99,212,223} If end-organ disease is observed, the diagnosis can be confirmed histopathologically by detection by PCR of EBV DNA in tissue or by in situ hybridization with an EBV-encoded RNA probe.^{4,251}

The diseases associated with EBV also may be classified in the laboratory as polyclonal or monoclonal. Polyclonal illnesses seem to be more benign than are monoclonal diseases, which often are associated with chromosomal abnormalities and malignant transformation.¹⁹⁵ The virus cannot be cultivated by routine means; when studied by special culture techniques, EBV has been found frequently in the oropharyngeal secretions of seropositive transplant recipients and is not predictive of EBV-associated disease.^{195,212} Similarly, serologic approaches to establishing the diagnosis of EBV infection after a transplant procedure also are nonspecific and difficult to interpret in most patients unless the recipient clearly has seroconverted during the posttransplant period.

Aggressive or intense treatment of uncomplicated EBV-associated viral syndrome or mononucleosis usually is unnecessary because these illnesses seem to be self-limited in most patients. Immunosuppression may be reduced, and acyclovir may be administered; the patient should be monitored carefully. If symptoms in the patient or EBV DNA levels in the blood persist or increase, PTLD should be suspected and the diagnosis should be confirmed.^{245,252}

Treatment of established PTLD is challenging.⁹⁶ Mortality rates are high, and the best results seem to occur if the disease is diagnosed by quantitative PCR viral-load monitoring and serial imaging studies and treated aggressively.²⁵¹ Preemptive therapy instituted when viral surveillance monitoring detects an increase in EBV DNA in circulating lymphocytes before end-organ disease is evident also may be helpful in some patients.^{4,54,154} Reduction in immunosuppression remains the most widely recommended strategy, but a variety of regimens have been studied as well.

Antiviral agents such as acyclovir and ganciclovir seem to reduce EBV replication early in the course of the disease process and may halt the progression of disease in some patients.^{63,197,265} Antiviral agents are ineffective, however, against latent EBV or cells that have been transformed by the virus. Interferon- α , immunoglobulin, and anti-CD20 monoclonal antibody preparations such as rituximab have been used successfully in patients with established PTLD. Experimental protocols evaluating adoptive immunotherapy in transplant recipients are ongoing. In addition, some experts suggest that administration of intense anti-CMV therapy with ganciclovir and CMV hyperimmune globulin may improve chances of survival in certain patients with PTLD because CMV may serve as a cofactor in progression of disease caused by other members of the Herpesviridae.^{1,20,66,200,236,250} Treatment of patients with lymphoma or leiomyoma includes a reduction in immunosuppression, chemotherapy, radiation therapy, and surgical resection of tumors.

Varicella zoster virus. VZV can cause primary (varicella, chickenpox) or reactivation (zoster, shingles) disease in a renal transplant recipient.^{195,237} Infection with VZV can occur at any time but does so most often during the middle posttransplant period. Patients have fever and painful or pruritic vesicular skin lesions.¹⁸⁰ Hepatitis, encephalitis, acute or chronic recurrent cerebral vasculitis and vasculopathy, and pneumonia also may occur, even in the absence of skin lesions, especially in an immunocompromised host.¹¹³ Varicella occurs more frequently in children, and zoster occurs more frequently in adolescent and adult transplant recipients.¹⁴

In contrast to other herpesviruses, VZV almost always is transmitted person to person or by aerosol in health care, family, and community settings; it rarely, if ever, has been linked to the transplanted allograft.^{164,195} Before the advent of routine immunization and antiviral therapy, infection with VZV was a major cause of morbidity and mortality in children receiving solid-organ transplants.^{44,77,219} Untreated primary varicella may

continue for several weeks and result in visceral dissemination, pneumonitis, hepatic necrosis, encephalitis, vasculitis with stroke, disseminated intravascular coagulation, hemorrhagic skin lesions, and death.^{77,197,227} Zoster in solid-organ transplant recipients may remain localized to a dermatome, but it often disseminates beyond the dermatomal distribution and produces widespread skin lesions and even visceral dissemination.

The diagnosis of VZV disease often is clinical, but it should be confirmed by isolation of VZV from fresh, vesicular skin lesions or detection of viral antigen by direct immunofluorescence assay on cells obtained by scraping the base of the skin lesion.¹⁹⁷ Tzanck smear may show multinucleated giant cells, suggesting a viral infection, but it cannot differentiate VZV from HSV. Other pathogens, especially HSV, may mimic VZV disease, so establishing an accurate viral diagnosis is important. VZV also may be detected by PCR-based DNA detection methods, which also may distinguish wild-type strains from the OKA vaccine strain of VZV; qualitative and quantitative VZV PCR tests may be performed by reference and research laboratories. Establishing a serologic diagnosis of active VZV infection is difficult. Routine serologic screening performed in the pretransplant period identifies patients who are seronegative and at risk for developing primary infection with VZV.

Treatment of established VZV disease should be instituted as early as possible during the course of the illness because survival is improved if treatment begins before the fifth day of illness.⁷⁷ Acyclovir is recommended for most renal transplant recipients experiencing either primary infection with varicella or zoster with dissemination; it is administered intravenously in high doses (500 mg/m² per dose every 8 hours if renal function is normal or adjusted for renal function as needed) for 5 to 10 days, or until new lesions have ceased to occur for 24 to 48 hours, old lesions have crusted, the fever has resolved, and disease has abated.^{32,189,195,265} Uncomplicated zoster or very mild primary varicella may be treated with oral acyclovir, famciclovir, or valacyclovir, provided that the patient is monitored carefully for clinical response. Ganciclovir, foscarnet, or cidofovir also provide cross-cover protection for most VZV strains, if these antiviral agents are being administered for difficult CMV infections. If acyclovir-resistant varicella develops, then treatment with foscarnet or a combination of two or three antiviral agents may be necessary to control the infection.

Prevention of posttransplant VZV disease can be accomplished by several effective strategies, which should be discussed during the pretransplant evaluation. Transplant recipients who were seronegative for VZV during the pretransplant evaluation should receive varicella vaccine before undergoing transplantation, if possible.^{84,131,275} Pretransplant varicella vaccination is safe, beneficial, and cost effective when administered to pediatric renal transplant candidates and in selected renal transplant recipients after a transplant procedure.^{32,43,84,85,189}

Seronegative, unimmunized transplant recipients who are exposed to varicella or zoster during the posttransplant period should receive passive immunoprophylaxis with varicella zoster immunoglobulin (VariZig). Preemptive therapy with oral acyclovir also is recommended by some experts in this situation because varicella zoster immunoglobulin does not prevent, but only attenuates, the postexposure disease process. Finally, acyclovir, valacyclovir, ganciclovir, and valganciclovir administered prophylactically to transplant recipients who are seropositive for HSV or CMV also may provide protection against VZV disease.^{143,195}

Human herpesviruses types 6, 7, and 8. HHV-6, HHV-7, and HHV-8 also infect renal transplant recipients by primary infection and by reactivation.^{41,42,48,74,108,217,218,236} Infection with these viruses becomes evident during the middle posttransplant period, but their roles in specific disease processes are unclear.^{197,230,246} HHV-6 and HHV-7 may act as cofactors in the progression of a disease, especially diseases caused by CMV and EBV.^{74,129,180,191,250} HHV-8 is associated with Kaposi sarcoma after a transplant procedure in severely immunosuppressed adult renal transplant recipients, but to date it has not been appreciated as a major opportunistic pathogen in pediatric renal transplant recipients.^{41,44,76,195,209,225} HHV-8 may be transmitted through the renal allograft or by blood product transfusion, or it can become reactivated in the recipient after transplant surgery.²⁰⁹

Polyomaviruses and Papillomaviruses

Polyomaviruses. Human polyomaviruses (JC, BK, and SV40) frequently infect children and are present in urine and stool.^{258,259} They can be

detected in the urine of 33% to 58% of renal transplant recipients and detected serologically in 56%, and they are found histopathologically and by PCR in blood, body fluids, and tissue in 8% to 13%.^{*} Knowledge about the roles that these viruses play in the outcome of renal transplant patients is evolving.

The JC and BK polyomaviruses seem to have a significant impact on adult and pediatric renal transplant recipients.^{6,24,86,153,170,181,183,210,221} BK virus has been implicated in various syndromes, including ureteral stenosis, hemorrhagic or chronic cystitis, interstitial nephritis with graft failure, allograft nephropathy (BK-associated nephropathy [BKAN]), and rejection, in renal transplant recipients.[†] Disease associated with these viruses most often occurs during the middle and late posttransplant periods. BK virus may be asymptomatic or cause increasing serum creatinine levels, cystitis, tubular necrosis, graft dysfunction, or allograft rejection.^{192,207} Risk factors for BKAN seem to include BK serostatus at the time of transplant, greater immunosuppression with use of mycophenolate mofetil, and concurrent CMV infection.^{72,88,89,107,146,253}

Ciprofloxacin prophylaxis in kidney transplant recipients has been shown in one recent study to reduce BK virus infection and BKAN 3 months posttransplant, but not at 1 year posttransplant.²⁷⁰ BK virus historically was detected in urine by the presence of “decoy cells,” which are cells containing intranuclear viral inclusions. Currently quantitative PCR assays that detect and quantify BK viral DNA are used for detection. BK viremia precedes BK nephropathy, which precedes BK nephropathy.^{15,109} Patients with BK-associated nephropathy may have BK viral DNA detected in the urine, blood, or plasma, and renal biopsy specimens may show characteristic viral inclusions. Most recently quantitative PCR viral surveillance in blood or plasma has been shown in renal transplant recipients to be useful in predicting the development of BK nephropathy and in guiding preemptive antiviral and immunosuppressive strategies.

Pediatric kidney transplant recipients who have increasing BK viremia levels should be managed preemptively with carefully monitored reduction of immunosuppression to prevent development of more serious complications of BKAN and graft rejection.²⁰⁵ This strategy usually results in reduction and then clearance of BK viremia and development of BK-specific cellular immunity coincident with BK virus clearance.¹⁴⁶ Treatment of established BKAN includes a reduction in immunosuppression. Cidofovir and fluoroquinolones have activity against BK virus, and both have been used to treat BK virus infection and treat severe disease caused by BKAN.^{109,265} Intravenous immune globulin may also be of benefit; one report resulted in decrease of BK viremia and histologic resolution of BKAN.⁸

JC virus causes a rare syndrome called *progressive multifocal leukoencephalopathy*. It may be diagnosed by viral DNA detection using PCR-based assays available in reference and research laboratories or histopathologically by brain biopsy or autopsy examination. Successful treatment options for progressive multifocal leukoencephalopathy caused by JC virus are very limited, and most, if not all, patients die of progressive encephalopathy. An unusual case of JC virus encephalopathy transmitted from a donor kidney was successfully treated by removal of the donor organ.²²

Papillomaviruses. Human papillomaviruses are common viruses that infect healthy children, adolescents, and adults. Adult renal transplant recipients are at increased risk for development of human papillomavirus-associated disease, such as cervical cancer and anogenital papillomas, whereas pediatric patients may develop numerous disfiguring cutaneous warts posttransplant, especially if they require severe immunosuppression.^{186,195,211} Malignant transformation of cutaneous warts caused by high-risk types has been documented.²¹¹ Treatment options are limited but include physical removal of papillomas with laser and cryotherapy and careful reduction of immunosuppression. In one case series report, careful transition of the immunosuppression regimen from tacrolimus-mycophenolate to tacrolimus-leflunomide resulted in resolution of cutaneous warts in four pediatric renal transplant recipients.¹⁷⁹ Human papillomavirus vaccines in patients with ESRD or renal transplant

recipients are now recommended to be administered according to the standard immunization schedules.¹⁶²

Adenoviruses

Adenoviruses may infect pediatric renal transplant recipients at any time, but they are most likely to cause significant disease during the middle posttransplant period. They continue to emerge as a significant pathogen in pediatrics, including transplant recipients. They do not seem to play as important a role in renal transplant outcome, however, as do other viruses, such as the herpesviruses, and they currently are not as prominent in renal transplant recipients as they are in other transplant recipients, such as recipients of liver, lung, bone marrow, or stem cell transplants.^{94,159,187,195,197} Nonetheless infections with adenoviruses in pediatric renal transplant recipients, when they occur, can be serious and include hemorrhagic cystitis, diarrhea, allograft nephropathy, pneumonia, hepatitis, and disseminated disease with multisystemic involvement.^{25,128,218,248,257,268,272}

The diagnosis is made by isolation or detection by PCR of the virus in respiratory secretions, stool, urine, blood, or tissue. Rapid diagnosis may be accomplished within 30 to 60 minutes, using a rapid immunochromatographic assay that detects adenovirus antigens in eye secretions, respiratory samples, urine, and stool. Viral DNA also may be detected by PCR or quantitative PCR available in reference or research laboratories, and characteristic changes may be seen by histopathology in tissue. Adenovirus serotyping by neutralization assays and genotyping by PCR sequence-based assays are available in reference laboratories.⁹⁴ Treatment of serious adenoviral disease primarily is supportive. Immunosuppression also may be reduced, when possible. Antiviral agents, such as ribavirin, ganciclovir, and cidofovir, have activity against adenoviruses. Clinical reports of use of cidofovir in traditional weekly dosing and intermittent renal sparing dosing is safe and well tolerated in pediatric transplant recipients with adenovirus disease.^{21,40,67}

Human Erythrovirus (Parvovirus B19)

Human erythrovirus has been reported to cause acute and chronic infection, manifesting as chronic anemia, red blood cell aplasia, and pancytopenia in renal transplant recipients.^{55,118,120,132,208,262,269} It also has been implicated in collapsing glomerulopathy and thrombotic microangiopathy in renal transplant recipients.²⁶³ Unusual manifestations, such as hepatic necrosis or central nervous system infection with vasculitis, also have been reported.^{19,23,137,138} Transmission most likely is person to person; however, some reports indicate that the virus may be transmitted by blood product transfusion or in the renal allograft.^{18,19,136} More recent reports suggest that the role that this virus plays in the outcome of renal transplant recipients may be more important than previously recognized, but systemic studies in pediatric patients have not been done.¹⁸

The diagnosis of acute infection with human erythrovirus is supported by erythrovirus-specific IgG seroconversion; detection of erythrovirus-specific IgM antibodies in serum; or detection of viral DNA in plasma, blood, body fluids, bone marrow, or tissue. The virus is not cultivatable in clinical virology laboratories that use routine cell cultures, but laboratories using special erythroid precursor cell lines may be able to cultivate erythrovirus for research purposes. No specific antiviral therapy is available, but anecdotal experience and case reports support a beneficial role for intravenous immunoglobulin and carefully monitored reduction in immunosuppression as management strategies to resolve erythrovirus viremia and associated end-organ disease.¹⁶⁷

West Nile Virus

WNV is a single-stranded RNA flavivirus is an important pathogen worldwide. It usually is transmitted by mosquitoes and causes a febrile illness, viral meningoencephalomyelitis, and acute flaccid paralysis in the normal host. Renal transplant recipients may become infected with WNV that is transmitted by the organ donor, by blood product transfusions, or naturally from mosquitoes.^{55,118,120,132,208,262,269} Routine screening of solid-organ donors for WNV infection has been discussed but currently is not routinely performed.^{118,177} Infection with WNV may manifest in the early posttransplant period if it is transmitted by the graft or blood products and, because of immunosuppression, produce severe febrile

^{*}References 6, 68, 72, 80, 81, 86, 88, 89, 107, 109, 111, 114, 146, 170, 181, 182, 183, 192, 194, 204, 205, 221, 253.

[†]References 24, 49, 59, 68, 80, 81, 111, 114, 182, 194, 204, 211, 221.

illnesses, seizures with status epilepticus, encephalitis, paralysis, and movement disorders. Death also may occur.⁵⁵ A high index of suspicion is required; if WNV is suspected, serum and cerebrospinal fluid should be sent for WNV-specific IgG and IgM antibody testing. The virus also may be isolated in special cell cultures and detected by reverse transcriptase PCR-based assays or through metagenomic deep sequencing.²⁶⁹ Immunohistochemical staining may show WNV proteins in tissues from biopsy or autopsy examination. Outcome in renal transplant recipients with WNV disease improves with early establishment of the diagnosis and carefully managed reduction of immunosuppression.²⁰⁸

Zika Virus

Zika virus is another flavivirus that has emerged as an important global pathogen and that may potentially impact kidney transplantation. Zika virus causes a febrile illness with rash, conjunctivitis, headache, malaise, or muscle and joint pain. It may be transmitted from mosquitoes or through sexual transmission, by blood transfusions, or from mother to baby and cause congenital infection and congenital Zika syndrome.¹⁷³ The risk of Zika virus transmission through renal transplantation is unknown at this time, but the virus has been detected in the urine as well as the kidney and other organs of Zika-infected individuals.^{93,184} Routine screening of donors or recipients for Zika virus infection is not currently recommended unless there is a recent history of travel or exposure or illness associated with Zika virus within 6 months of kidney transplantation. Pretransplant evaluation should include a careful travel history within 6 months to an area with active Zika virus transmission and a history for signs and symptoms associated with Zika virus infection in either the donor or the recipient. Since the risk of Zika virus transmission through renal transplantation is unknown at this time, Zika virus infection or exposure is not a contraindication to renal transplantation, but the risk of donor-derived infection should be balanced with the potential benefits of transplantation in each potential renal transplant recipient.¹⁸⁴

Mycoplasma

Mycoplasma spp. commonly infect school-aged children. Children and adolescents who undergo renal transplantation also may experience respiratory tract infections with *M. pneumoniae* and *M. hominis*. The infection also may disseminate to extrapulmonary sites, causing hepatitis, septic arthritis, or perinephric fluid collections in pediatric renal transplant recipients.^{126,157,239} *Mycoplasma* spp. may be detected using special biphasic culture media or PCR-based assays. Serologic diagnosis is difficult to accomplish owing to cross-reactivity of antigens producing the possibility of false-positive reactions in some patients. Antimicrobial therapy with macrolide antibiotics, along with carefully managed reduction of immunosuppression, may be beneficial in selected patients.^{126,157}

Bacterial and Mycobacterial Diseases

Bacteria that commonly produce disease in renal transplant recipients during the middle posttransplant period include *L. monocytogenes*, which often causes sepsis or meningitis.^{195,232} Routine bacterial illnesses that were not identified and properly treated during the pretransplant period also may emerge at this time and cause abscesses, sepsis syndrome, and death.

Mycobacterial disease caused by *M. tuberculosis* may occur at any time after transplantation, but it occurs most frequently during the middle posttransplant period.^{141,144,195,206} *M. tuberculosis* causes disease in approximately 1% of renal transplant recipients in the developed continents, such as North America and Europe, and in 15% of renal transplant recipients in developing countries with a high prevalence of tuberculosis, such as India or Pakistan.^{123,195,206,213,222,224} Tuberculosis may develop in renal transplant recipients as a result of primary and reactivation infection in almost any site, and transmission from the renal allograft and reactivation in the native kidney have occurred.^{133,168,169,213} *M. tuberculosis* may cause various diseases, including pulmonary infiltrates, cavitary lesions, adenopathy, cutaneous lesions, bone and joint disease, liver or spleen granulomas, and meningitis. Fever frequently is noted, and miliary or disseminated disease may occur, especially in young children.

Because the TST is negative in most renal transplant recipients with active tuberculosis, the diagnosis is determined best by IGR assays, detection of acid-fast bacilli in smears from tissue or sputum, and isolation of *M. tuberculosis* in cultures of gastric aspirates, sputum, tracheal secretions, spinal fluid, or tissue.^{144,195} The presence of granulomas in tissue also suggests the diagnosis of tuberculosis.

Treatment of tuberculosis in a renal transplant recipient usually includes isoniazid, rifampin, and pyrazinamide for 1 year, although shorter courses may be acceptable in some patients.^{141,195} Other antituberculous drugs may be added to or substituted for this standard regimen, depending on the disease process, the susceptibility pattern of the organism, and potential drug interactions. Because many antituberculosis drugs are excreted by the kidney, doses may need to be adjusted in a renal transplant recipient. Because rifampin may interact with cyclosporine, levels of cyclosporine should be monitored closely to avoid rejection of the allograft.¹⁸⁵ If a history of tuberculosis exposure is elicited during the pretransplant evaluation, the transplant candidate should be evaluated for tuberculosis, including having a TST, IGR assay on blood, and chest radiograph.^{168,169,206} All close contacts also should be investigated for evidence of having tuberculosis. Treatment is recommended if disease is discovered, and prophylaxis with isoniazid is indicated for most patients who have a recently positive result of a purified protein derivative (PPD) test on pretransplant evaluation.^{141,195,197,224,274} A transplant recipient who receives an allograft from a donor with a history of tuberculosis or a positive TST or IGR assay also may be a candidate for prophylaxis with isoniazid after a transplant procedure.^{141,195,197}

Atypical mycobacteria are ubiquitous nontuberculous mycobacteria that can infect and produce disease in renal transplant recipients. They can cause disease during the middle posttransplant period and so are included here. Their effects usually do not become evident, however, until many years after the patient has undergone transplantation, during the late posttransplant period.^{53,169,198} Atypical mycobacteria that have been documented to cause disease in solid-organ transplant recipients include *M. kansasii*, *M. avium-intracellulare*, *M. fortuitum*, *M. xenopi*, *M. haemophilum*, *M. marinum*, *M. chelonae*, *M. abscessus*, *M. gastri*, *M. scrofulaceum*, and *M. thermoresistibile*.^{123,195,197}

A high index of suspicion is necessary to detect these elusive pathogens. They should be considered as the cause of disease in patients with persistent cutaneous ulcers, abscesses, adenopathy, pulmonary nodules, chronic wound infections, or bone and joint disease after negative routine bacterial cultures have been obtained and the patient has failed to respond to standard antimicrobial therapy.²¹⁸ Disseminated, multisystemic disease also can occur. Environmental sources of atypical mycobacteria include contaminated dialysis equipment, soil, and contaminated water in aquariums and pools. The diagnosis is established by isolation of nontuberculous mycobacteria in fluid or tissue. Granulomas are not observed consistently in tissue, and acid-fast stains may be negative.²¹⁸ Atypical nontuberculous mycobacteria are difficult to treat, and treatment must be individualized to each patient. Strategies include reduction of immunosuppression and surgical débridement of localized disease. Antimicrobial therapy based on in vitro susceptibility testing of the isolate also should be administered, often for a prolonged period.

Nocardia

Nocardia asteroides is the most common *Nocardia* spp. causing illness in renal transplant recipients; however, other, more unusual *Nocardia* spp., including *N. transvalensis*, *N. brasiliensis*, *N. nova*, *N. otitidiscauariarum*, and *N. farcinica*, also have been shown to cause disease in solid-organ transplant recipients.^{195,197,268} The most common manifestations of nocardial disease in transplant recipients are fever, cough, and pulmonary infiltrates.²⁶⁸ Pleural effusion, pulmonary nodules, and cavitary lesions also may occur. Cutaneous infection, adenitis, arthritis, meningitis with brain abscesses, and infection of the renal allograft also may occur. *Nocardia* spp. can be seen on Gram and modified acid-fast stains of sputum, bronchoalveolar lavage fluid, abscess fluid, and tissue. They can be isolated on routine media but may take longer than conventional bacteria to grow. Prolonged treatment with sulfonamides, alone or in combination with trimethoprim, is recommended. Amikacin

and other antimicrobial agents may be added in selected patients with severe disease, provided that renal function is monitored closely.²¹⁸ Trimethoprim-sulfamethoxazole prophylaxis for UTI and *P. jiroveci* also may be effective in preventing disease caused by *Nocardia*.

Fungal Diseases

Fungal infections occur infrequently in renal transplant recipients relative to other solid-organ transplant recipients.^{12,195,197,218} This lower rate of infection probably is related to technical procedures performed at the time of transplantation and the lower level of immunosuppression required to maintain most renal allografts.²¹⁸ When they do occur, however, fungal infections often are serious and life threatening.^{101,105,115} Fungal disease in a renal transplant recipient usually is manifested in one of two ways: (1) pulmonary or disseminated disease caused by one of the environmental mycoses, such as *H. capsulatum* or *C. immitis*, or (2) opportunistic infection with fungi that rarely cause disease in a normal host, such as *Candida* spp., *P. jiroveci*, *Aspergillus* spp., *Cryptococcus neoformans*, *Nocardia* spp., and others.^{101,234}

Travel to endemic areas increases a transplant recipient's risk for development of histoplasmosis and coccidioidomycosis and may be identified during the pretransplant evaluation. Factors that increase a transplant recipient's risk for acquisition of opportunistic fungal disease include underlying conditions such as diabetes mellitus, repeated episodes of rejection, long-term administration of corticosteroids, prolonged use of antibiotics, and CMV infection. Similar to tuberculosis, invasive fungal disease can be a result of primary infection or reactivation infection with secondary dissemination.²¹⁸ *P. jiroveci*, currently classified as a fungus, may cause pneumonia in 10% of solid-organ transplant recipients, most often during the first 6 months after a transplant procedure.^{9,195,197} It seems to occur more commonly in children than in adults and usually causes fever, dyspnea, tachypnea, hypoxemia, and a nonproductive cough.^{69,195} Interstitial pulmonary infiltrates are typical findings, but almost any radiographic picture can be observed, and pneumothorax is common in severe disease. The diagnosis can be suspected clinically but is documented best by organisms being shown in lung biopsy specimens; bronchoalveolar lavage may provide the diagnosis in some patients.

Treatment with high-dose oral or intravenous trimethoprim-sulfamethoxazole for 14 to 21 days is used most often. Intravenous pentamidine may be administered to selected patients, but renal function should be monitored carefully.²¹⁸ Corticosteroids may be helpful in treating severe disease if given early in the course. Low-dose oral trimethoprim-sulfamethoxazole provides effective prophylaxis against *P. jiroveci* pneumonia and UTIs and usually is administered to renal transplant recipients for at least 6 months posttransplant.⁸² Transplant recipients experiencing repeated episodes of rejection, allograft dysfunction, or CMV disease may require a longer period of prophylaxis.^{195,197} Aerosolized pentamidine is an alternative prophylaxis strategy for some patients.²¹⁸

Candida spp., especially *C. albicans*, are the opportunistic fungi most frequently isolated in renal transplant recipients.^{195,197} Other *Candida* spp. isolated include *C. krusei*, *C. glabrata*, and *C. tropicalis*, and others. The newly recognized *C. haemulonii* and *C. auris*, potentially fatal, multidrug resistant species of *Candida* causing health care–associated bloodstream infections, have not yet been documented in pediatric renal transplant recipients but remain a potential risk for these patients.³⁶ Most fungal infections caused by *Candida* spp. occur during the first 2 months after transplant surgery, usually at the site of indwelling intravascular and urinary catheters.²¹⁸ Esophagitis, abscesses, and arthritis also can develop, and endocarditis with metastatic foci can occur if the fungemia persists. Other opportunistic fungi such as *Aspergillus* most often cause sinusitis and pulmonary disease, and, because of its angioinvasive nature, *Aspergillus* often disseminates and causes lesions in the liver, spleen, and brain.^{195,197,234,235}

A thorough search for metastatic foci always should be undertaken when a primary focus of invasive fungal disease is documented. *C. neoformans* usually causes cutaneous lesions or abscesses and pneumonia with pleural effusion, but meningitis, arthritis, and pyelonephritis also can occur.^{195,197,229} Exposure to soil or bird droppings provides an epidemiologic clue to the diagnosis. In addition, the Zygomycetes,

including *Rhizopus*, *Mucor*, *Rhizomucor*, and *Absidia* spp., can cause disease in solid-organ transplant recipients.^{234,235} They most often cause cutaneous, rhinocerebral, or pulmonary disease or brain abscesses in renal transplant patients. Cutaneous and soft tissue infections, wound infections, and gastrointestinal disease with perforation also have been described. The Zygomycetes, similar to *Aspergillus*, are angioinvasive and disseminate via the bloodstream to cause disease, which often is severe. A variety of unusual fungi, such as *Paecilomyces*, *Fusarium*, and *Bipolaris*, have been shown to cause cutaneous infection, usually at the site of indwelling catheters, and *Hansenula anomala* reportedly has caused UTI in a renal transplant recipient.⁹¹

The endemic dimorphic fungi include *H. capsulatum*, *C. immitis*, *B. dermatitidis*, and *Paracoccidioides brasiliensis*. Infection with these organisms can occur at any time after the patient has undergone transplantation but usually occurs during the intermediate posttransplant period.²⁴⁹ These organisms usually are noted in renal transplant recipients who reside in endemic areas. Histoplasmosis is endemic in the central part of the United States and many foreign countries, and nosocomial outbreaks have occurred during hospital construction projects. Fever, chills, and cough are the usual initial signs. Skin lesions, hepatosplenomegaly, and meningitis also can occur. Pancytopenia often is present as well, and the organism frequently is found in the bone marrow of patients with disseminated disease. Coccidioidomycosis is endemic in the southwestern portion of the United States and northern Mexico. It usually is manifested as fever, cough, and pulmonary infiltrates, but extrapulmonary dissemination frequently occurs. Blastomycosis is endemic in the southern United States, along the Mississippi and Ohio River valleys, and in the Great Lakes area. It is a rare development after renal transplantation, but most often causes lung and skin lesions. Paracoccidioidomycosis rarely has been reported in renal transplant recipients.²⁴⁴

The diagnosis of invasive fungal disease is established best by isolating the fungus from sputum or tracheal aspirate, bone marrow, tissue, or fluid. Serum tests and bronchoalveolar lavage for galactomannan and 1-3- β -D-glucan levels support the diagnosis of invasive fungal disease, and DNA PCR tests on serum and bronchoalveolar lavage fluid also may now be performed to detect *Candida* spp. and other fungi.¹²

C. neoformans also may be isolated from urine. Fungal-specific serology and tests for cryptococcal antigen may support the diagnosis of cryptococcal infection.²⁴⁴

Fungal identification and susceptibility testing now can be performed in clinical and reference laboratories and should be used to guide therapy whenever possible. Amphotericin B usually is used to treat most invasive fungal disease in transplant recipients, and the deoxycholate, lipid complex, or liposomal forms can be used, provided that renal function is monitored closely.¹⁴² Flucytosine may have additive or synergistic effects against many yeasts and fungi. The azole antifungal agents are not nephrotoxic and are used in renal transplant recipients whenever possible. Many *Candida* spp. are susceptible to fluconazole, although resistance is emerging in all *Candida* spp. and is present in a high percentage of *C. krusei* and *C. glabrata*. Itraconazole and voriconazole may be effective against other fungi, such as *Aspergillus*.¹² Voriconazole is the treatment of choice for most *Aspergillus* infections. Itraconazole should be used with caution because it has variable oral absorption and may interact with cyclosporine.²⁴⁹ Caspofungin, an echinocandin, also has activity against most *Candida* spp. and a variety of opportunistic fungi, including some species of *Aspergillus*. The triazole posaconazole and the echinocandin micafungin have also been used successfully in pediatric renal transplant recipients with invasive fungal disease.

Surgical resection or drainage of abscesses, avascular cavities, or effusions may be required to treat some forms of invasive fungal disease of the lungs, liver, or spleen. Carefully monitored reduction in immunosuppression also may help the host recover from invasive fungal disease.

Parasitic Infections

The parasites most commonly encountered in renal transplant recipients during the intermediate posttransplant period are *T. gondii*, *S. stercoralis*, and *Trypanosoma cruzi*.^{78,195} These infections occur most often in adults. Children also may be infected with routine parasites such as *Enterobius*

vermicularis, *Ascaris*, *Giardia*, and others before a transplant operation. Other parasitic infections that may be found in renal transplant recipients include leishmaniasis, schistosomiasis, and malaria. Renal transplant recipients seem to be at much lower risk for acquisition of parasitic diseases than are other solid-organ transplant recipients.

Infection with *T. gondii* usually occurs as a result of reactivation of latent disease in the donor allograft or recipient.¹⁴⁹ It is encountered most frequently in heart transplant recipients, but any solid-organ recipient, including renal transplant patients, may be affected. Clinical manifestations of infection with *T. gondii* include focal meningoencephalitis, brain abscesses, pneumonia, myocarditis, pericarditis, hepatitis, and retinochoroiditis.^{163,240,249,256} The diagnosis may be made by demonstration of the organism in tissue by histopathology, detection of DNA by PCR in body fluids or tissue, or serologically by detection of high titers of IgG and specific IgM antibody to *T. gondii*. Treatment with pyrimethamine, sulfadiazine, and folinic acid usually is recommended; however, some patients also may respond to clindamycin. Routine prophylaxis with trimethoprim-sulfamethoxazole for UTI and *P. jirovecii* infection may help prevent disease with *T. gondii*.

S. stercoralis is an important pathogen in adult transplant recipients, but it is rarely, if ever, a significant problem in pediatric patients. Because *S. stercoralis* can be maintained in the human intestinal tract for decades, it can disseminate and cause serious disease in transplant recipients who were infected before the procedure. A complete blood cell count for eosinophilia should be obtained, and stool and other specimens should be examined for rhabditiform larvae if the pretransplant evaluation reveals travel to endemic areas. Thiabendazole should be given before transplantation is performed if *S. stercoralis* infection has been documented or is suspected. *T. cruzi*, the cause of Chagas disease, rarely has been transmitted by renal transplantation.^{78,139}

Infections Occurring During the Late Posttransplant Period

Infections occurring 6 months or more after the patient has undergone renal transplantation usually are less severe than infections experienced in the earlier periods, especially if the level of immunosuppressive therapy is low and the allograft is functioning well.²¹⁷ Constant vigilance for health care–associated and community-acquired viral and bacterial diseases and unusual infections should continue, however.

Chronic rejection or repeated episodes of acute rejection complicated by allograft dysfunction predispose the patient to development of more serious opportunistic infections, similar to infections encountered during the first 6 months after a transplant. UTIs that develop during this period, in contrast to UTIs in the early posttransplant period, usually are benign, especially if the patient is afebrile, and may be treated with conventional antimicrobial therapy in most instances if they do not seem to threaten the function of the allograft or the patient's survival. Patients also may experience community-acquired infections with respiratory viruses, such as influenza virus and respiratory syncytial virus, and with bacteria, especially *Streptococcus pneumoniae* (pneumococcus) or *S. aureus*. These common community-acquired bacterial pathogens may be resistant to usual β -lactam antibiotics.^{241,254} In addition, patients vaccinated with 7-valent or 23-valent pneumococcal vaccines still may acquire invasive pneumococcal disease with emerging, nonvaccine serotypes, such as 19A and 3A. These serotypes often are also multidrug resistant. Opportunistic viral infections encountered during this period are zoster or, rarely, CMV retinitis.¹⁷² The risk for developing PTLN and BKAN also persists during this late posttransplant period.

Renal transplant recipients may be chronically infected with HBV or HCV before a transplant is performed. Increased risk for mortality from fulminant hepatitis with hepatic failure may occur during the early pretransplant period, and chronic liver disease, cirrhosis, and liver failure may be seen 10 years or more after renal transplantation has been performed in hepatitis B surface antigen (HBsAg)–positive recipients.²⁷³ All transplant recipients who are not immune to HBV should receive HBV vaccine before transplantation.²⁶⁴ Most experts agree that renal allografts from HBsAg-positive donors should not be used, but the decision to perform renal transplantation in recipients

who are HBsAg-positive is controversial and must be made on an individualized basis.

Renal transplant recipients who are infected with HCV before the transplant usually do well during the early posttransplant period, but long-term survival is poorer than in recipients who are not infected with HCV. Not only can chronic liver disease develop, but also membranoproliferative glomerulonephritis has been reported in renal transplant recipients infected with HCV.³³ Despite these risks, however, most experts do not consider infection with HCV a contraindication for renal transplantation in patients with ESRD.²⁰¹ Hepatitis G virus also has been detected in the serum of renal transplant recipients, and at least one association with membranous glomerulonephritis has been reported.^{16,17} The role of HGV in clinical disease in renal transplant recipients is not established, however.

HIV may be transmitted by kidney transplantation despite routine screening of donors of blood and organs.^{136,211} A transplant recipient also may become infected with HIV after undergoing transplantation.¹⁹⁵ Shortly after a patient has undergone transplantation, HIV infection may cause fever and a mononucleosis-like syndrome. Complications of acquired immunodeficiency syndrome may develop during the late transplant period. HIV-infected patients with ESRD are no longer excluded from receiving renal transplantation because recent studies have shown successful outcomes.^{103,106,174,195}

The development of biomaterials used in the manufacturing of temporary or permanent implantable prosthetic devices has been one of the greatest advances in modern medicine.^{94,119,120} These devices have become an integral and important part of the current practice of medicine and have improved considerably the lives and health of countless patients. In the United States, the number and types of permanent prosthetic devices implanted to replace diseased or damaged body parts has increased substantially during the past several decades. An estimated 3 million or more people in the United States currently have some type of long-term biomedical implant.^{108,434,511} Box 74.1 lists implantable prosthetic devices discussed in this chapter.

One of the major medical complications associated with the use of implantable prosthetic devices is infection, which may result in serious tissue destruction and dysfunction of the prosthetic device or in local and systemic consequences that may be life threatening. In most cases, these infections are very difficult to cure with antimicrobial agents alone, and removal of the device usually is required for resolution of the infection.

INTERACTION OF THE HOST WITH A PROSTHETIC DEVICE

The prosthetic devices currently in use are composed of a variety of biomaterials, including cobalt-chromium-molybdenum alloy, titanium alloy, and complex polymers such as polytetrafluoroethylene, silicone, and polyethylene, which in general are chosen for their inert, nonreactive, and nontoxic qualities. The interplay of both implant and host factors determines the risk for acquiring and the severity of infection. The human body has numerous well-developed defense mechanisms to protect it against possible invasion by various microorganisms. Such mechanisms include cellular and humoral immune systems, anatomic barriers, and an elaborate network of cells that phagocytize and destroy invading organisms. The presence of a foreign body may compromise one or more of these defenses and elicit a complex acute or chronic inflammatory response (or both) from the host. Many of these devices breach cutaneous and mucosal barriers, thereby creating a direct route by which bacteria and fungi may invade. In addition, implanted devices may alter the local immunity of the host directly or indirectly.^{119,434,511,540}

Shortly after being implanted, hydrophobic polymeric materials such as polyethylene, Dacron, polydimethylsiloxane, and polyether urethanes become coated with a layer of host proteins such as plasma and interstitial fluid proteins (i.e., fibronectin, albumin, laminin, collagen, immunoglobulin G, fibrinogen) that bind to and are absorbed readily into the surface of the implant.^{35,386,512} This protein layer (especially fibrinogen) has a major influence on the body's response to and the biocompatibility of the implant. The presence of fibrinogen attracts a large number of phagocytic cells (i.e., neutrophils, monocytes, and macrophages) to the implant; these cells interact with the implant surface and initiate an acute inflammatory response.^{119,511} Some of these host proteins also serve as a receptor for various colonizing microorganisms. Collagen, laminin, and fibrinogen have been reported to play a role in adherence of bacteria,⁵⁴⁵ and fibronectin has been found to be the major receptor for gram-positive cocci, especially *Staphylococcus aureus*.^{418,523}

Chronic inflammatory responses, also known as *foreign body reactions*, are seen around many types of biomaterial implants and arise from interactions among the protein-coated surfaces of the implant and host tissues and adhering phagocytic cells such as macrophages and foreign body giant cells. These interactions may result in degradation and damage to the implant from the continuous generation of toxic catabolites and

release of inflammatory mediators such as hydrolases, activated complement components, tumor necrosis factor (TNF), interleukins, prostaglandins, coagulation factors, and plasminogen activator by the phagocytic cells.^{511,540,507}

INTERACTION OF MICROORGANISMS WITH A PROSTHETIC DEVICE

Once a prosthetic device is implanted, the surface of the device provides a potential area for adherence and multiplication of bacteria. Adherence is a complex process that involves electrostatic attachment of the bacteria to the surface of the implant, bacterial mechanisms that function specifically in attachment, and host-derived substances that coat the prosthetic device and serve as receptors for various bacteria. Bacteria arrive at the surface of the implant by many different routes; they may be inoculated at the time of implantation, the patient may have episodes of transient bacteremia, the device may be exposed by local trauma or infection, or the device may be implanted within an area in which the organism is part of the normal flora.^{108,119}

Adherence of bacteria to the surface of an implant is influenced by numerous different factors, including the material used to make the device, the source of the device material (adherence is greater with synthetic material than with biomaterial), the surface of the device (i.e., irregular more than regular, textured more than smooth, hydrophobic more than hydrophilic), and the shape of the device.¹⁰⁸ Cell surface molecules or structures known as *adhesins* also play a role in adherence by attaching or binding an organism to specific receptors on implant surfaces; different bacteria use different adhesins to attach to and colonize medical implants. For example, *Staphylococcus epidermidis* uses proteinaceous autolysin and capsular polysaccharide intercellular adhesin for initial adherence to the implant surface and for adherence of bacteria to each other. These bacteria also produce a biofilm that increases cell-to-cell association and allows accumulation of bacteria.⁴⁴² *Streptococcus pyogenes* uses lipoteichoic acid as its adhesin, whereas *S. aureus* uses both lipoteichoic acid and host-tissue ligands (e.g., fibronectin, fibrinogen, and collagen) for adherence. Binding of *S. aureus* to host-tissue ligands is mediated by genetically defined microbial surface proteins known as *microbial surface components recognizing adhesive matrix molecules* (MSCRAMM).¹⁰⁹ *Escherichia coli* and other bacteria use fimbriae as an adhesin to mediate binding to receptors on the surfaces of target cells.

Bacteria also can protect themselves from host defenses by synthesizing and excreting numerous complex polysaccharides, known as *glycocalyxes*, that function either as part of the bacterial capsule or as the slime layer. This slime layer is known to play a major role in keeping an organism attached to an implant surface by coalescing with the polysaccharides of other bacteria and with host products to produce a thick, adherent, and somewhat impenetrable biofilm.⁵⁴¹ The biofilm functions by trapping nutrients and protecting the organism from phagocytosis, antimicrobial agents, and competing microflora. It also plays a role in inhibiting the response to chemotactic stimuli, increases both *N*-formyl-methionyl-leucyl-phenylalanine (FMLP)-induced superoxide generation and release of specific granules, and impairs natural killer cell function while also altering the composition of T-lymphocyte cell subpopulations.^{176,179,236,541} Therefore the biofilm aids bacteria in evading host cellular and humoral defense mechanisms and thereby allows the organism to colonize and infect an implanted device effectively.

Substantial progress has been made in our understanding of the pathogenesis, prevention, and treatment of foreign body infections; this increased knowledge has resulted in a dramatic decrease in the morbidity associated with these infections, as well as subsequent

BOX 74.1 Partial List of Implantable Devices Prone to Infection

Central nervous system shunts
 Intracranial pressure monitors
 Intrathecal pump infusion
 Orthopedic prostheses (artificial hip, knee, and other joints; screws, pins, plates, and rods)
 Intracardiac pacemakers and defibrillators
 Left ventricular assist devices
 Extracorporeal membrane oxygenation circuits
 Ocular prostheses (artificial globes, intraocular lenses, ocular explants)
 Cochlear implant devices
 Tissue expander devices

improvement in the patient's quality of life. The following sections discuss specific device-related infections and the suggested treatment and management of these infections.

TISSUE EXPANDERS

The use of soft tissue expansion in reconstructive surgery was reported in the literature first in 1957, and since that time it has been used widely for the correction of multiple problems in plastic and reconstructive surgery in the adult and pediatric populations.^{21,30} These expanders consist of an alloplastic prosthesis with a filling port that is implanted into a subcutaneous pocket. The expander is filled with saline through the filling port at various intervals to create adequate expansion of the skin. Subsequent improvements of this technique led to the development of osmotic tissue expanders. The Osmed osmotic tissue expander is made of an osmotically active hydrogel (vinyl pyrrolidone and methyl methacrylate) in a silicone construct. When implanted, water is drawn from the surrounding tissues into the device, which can spontaneously expand up to 10 times its original volume. In children, tissue expansion is used most commonly to provide coverage for skin defects caused by burns, trauma, hemangiomas, and other congenital deformities.^{61,91,326,373,508,572}

The most common complication of tissue expansion is infection of the subcutaneous expander pocket, usually with skin organisms introduced during insertion of the expander.³⁹³ Cellulitis of the overlying skin and hematogenous or lymphatic seeding of the expander pocket are seen as well but occur much less frequently.^{21,154,165,221,318,326,365} In several pediatric case series, the infection rate ranged from 3.4% to 11%.^{1,165,326} *S. aureus*, *S. epidermidis*, and group A streptococci are the microorganisms recovered most commonly from these infections.^{165,221,321,326} Less commonly, nontypeable *Haemophilus influenzae*,³²⁶ *Pseudomonas aeruginosa*, *E. coli*, and *Actinomyces* spp.³⁴⁵ have been isolated from infections of expander pockets.³²¹

In cases of infection of subcutaneous pockets, treatment consists of removal of the tissue expander, debridement and drainage of the subcutaneous pocket, and administration of intravenous antibiotic therapy tailored to the organism isolated. For cellulitis of the overlying skin of an expander pocket, treatment with intravenous antibiotics but without removal of the tissue expander has been shown to be successful.²¹

The most common empirical antimicrobial therapeutic regimen consists of a first-generation cephalosporin or an extended-spectrum, penicillinase-resistant penicillin. For all of the infections of prosthetic devices discussed in the chapter, empirical antistaphylococcal coverage should include agents effective against community strains of methicillin-resistant *S. aureus* (MRSA) if warranted by their frequency in the area.

Therapy is tailored once the organism has been identified and its antibiotic susceptibility has been determined.

COCHLEAR IMPLANTS

During the past several decades, cochlear implantation has emerged as one of the best methods of providing auditory rehabilitation for the

profoundly deaf (congenital or acquired). The goal of this surgery in young children is to provide hearing that is adequate to facilitate the development of receptive and expressive language. The surgical technique involves the creation of a C-shaped flap in the postauricular and parietal-occipital scalp skin areas, elevation of the flap, implantation of a multichannel prosthesis, and insertion of an electrode array into the cochlea through openings drilled into the temporal bone.^{97,102,312}

The most common infectious complications associated with these implants are cellulitis of the overlying skin flap,³⁰⁵ acute mastoiditis,^{143,429} meningitis, otitis media, and delayed cochlear implant infections leading to extrusion of the implant.* Rates of infection range from 0.3% to 0.5% for meningitis, 2% to 12% for cellulitis of the skin flap and delayed cochlear implant infections, and to 36% for otitis media. The reported cases of meningitis have occurred in association with leakage of cerebrospinal fluid (CSF) in persons with a malformed cochlea who undergo cochlear implantation, as a consequence of intracranial spread of a developing middle ear infection along the electrode pathway, or via pneumococcal bacteremia with hematogenous seeding of the cochlea—for example, at a site of tissue necrosis related to the electrode or positioner with contiguous spread to the CSF and meninges. In June 2002, the U.S. Food and Drug Administration (FDA) received numerous reports of bacterial meningitis in children with cochlear implants who were younger than 6 years when they received the implants. The most common causative organism identified was *Streptococcus pneumoniae*, followed by nontypeable and type b *H. influenzae*. Other less common organisms that have been reported include *S. pyogenes*, *Acinetobacter baumannii*, *E. coli*, and *Enterococcus* spp.⁴³³ The incidence of pneumococcal meningitis in this group of patients was calculated to be 138.2 cases per 100,000 person-years—more than 30 times the incidence in the same-aged cohort in the general population. This increased incidence of meningitis was found to be associated strongly with the use of a cochlear implant with a positioner (a wedge-shaped insert that facilitates transmission of the electrical signal by pushing the electrode against the medial wall of the cochlea) in conjunction with the presence of radiographic evidence of a malformation of the inner ear and leakage of CSF. Cochlear implants with a positioner were voluntarily recalled in the United States in July 2002, although removal of existing implants containing a positioner was not recommended; use of appropriate vaccination against *S. pneumoniae* and type b *H. influenzae* was strongly recommended.^{28,50,174,433} On February 24, 2010, a 13-valent pneumococcal conjugate vaccine (PCV13) was licensed by the FDA. This vaccine contains polysaccharides of the seven serotypes in PCV7 and polysaccharides from six additional serotypes. This vaccine replaces PCV7 for all scheduled doses of PCV7 in infants. A supplemental dose of PCV13 is recommended for children 14 months through 18 years of age with a cochlear implant.² Children with cochlear implants may have a higher risk for middle ear infections because of several factors, including the naturally high incidence of acute otitis media in this population, the presence of a foreign body in the area of the infection, and the potential for spread of the infection into the cochlea along the electrode pathway. In a study of 50 children who received cochlear implants between 1991 and 1995, researchers found that children prone to the development of otitis media before undergoing implantation were at higher risk for developing postimplantation acute otitis media but responded well to routine oral antimicrobial therapy. The overall prevalence and the severity of acute otitis media were not found to be increased in children with cochlear implants.³⁰⁹

In cases of cellulitis of the skin flap, intravenous antimicrobial therapy should include empirical broad-spectrum antimicrobial agents effective against community strains of MRSA, methicillin-susceptible strains of *S. aureus*, and group A streptococci. Empirical antimicrobial therapy for meningitis usually consists of vancomycin and a third-generation cephalosporin that is tailored to the organism isolated. An exception is for children with the onset of meningitis during the first 2 weeks after cochlear implantation; in these instances, causal bacteria may include a broader range of pathogens, including gram-negative bacilli and gram-positive bacteria. Selection of a combination of antimicrobial agents that provides broader-spectrum coverage against gram-negative

*References 47, 100, 101, 105, 111, 168, 189, 195, 204, 205, 215, 226, 228, 304, 341, 366, 384, 565.

bacilli should be chosen. For delayed development of cochlear implant infections, therapy consists of removal of the implant and administration of intravenous antibiotics.^{434,440}

OCULAR PROSTHESES

The ocular prosthetic devices include artificial globes used primarily for cosmetic purposes, orbital implants, ocular explants, intraocular lenses, and contact lenses.

Orbital Implants

Orbital implants are made of hydroxyapatite or porous polyethylene and frequently are used in orbital reconstruction after enucleation or evisceration surgery. Infection of these implants is a rare event, with only a handful of cases reported in the literature.^{6,167,214,240,247,139,584} Patients most commonly report anophthalmic socket pain or discomfort, pain with eye movement, and excessive conjunctival edema and irritation while wearing an artificial globe.²³⁸ Papillary conjunctivitis of the socket with exudate and sometimes dehiscence of the overlying conjunctiva also may be seen.^{166,357} Infection may develop months to years after placement of the implant, and severity ranges from cellulitis to the development of an abscess around the implant itself, with implant extrusion. In a retrospective clinical case series of 103 patients who underwent hydroxyapatite implant insertion at one institution, patients who had a freestanding polycarbonate peg placed to enhance the motility of their ocular prostheses had a significantly higher rate of infection than those patients with nonpegged hydroxyapatite implants, at 42.9% versus 19.5%.¹⁴⁰

Radiographic studies that can aid in the detection of these types of infection include technetium 99m-labeled leukocyte scintigraphy, which is most useful in detecting early low-grade graft infection,²³⁷ and computed tomography (CT) and magnetic resonance imaging (MRI), which are useful later in the course of the infection to detect the presence of abscesses and structural tissue changes. Gram-positive cocci, primarily *S. aureus*, and coagulase-negative staphylococci are the organisms associated most commonly with these infections; however, *H. influenzae*, *S. pneumoniae*, α -hemolytic streptococci, *Capnocytophaga*, *Pseudomonas*, and *Aspergillus fumigatus* have been cultured as well.^{92,433,441,468,497,577,585} To cure the infection effectively, treatment involves both removal of the implant and institution of topical and parenteral antibiotic therapy directed against the organism isolated. Empirical therapy directed against gram-positive organisms may be started initially until the results of culture and sensitivity testing are available. This should include antimicrobial agents effective against community strains of MRSA. In addition, other common empirical regimens include a first- or second-generation cephalosporin or an extended-spectrum, penicillinase-resistant penicillin.

Intraocular Lenses

Insertion of polymethyl methacrylate (PMMA) intraocular lenses at the time of removal of a cataract is the standard surgical therapy for this disorder. Even though the rate of postoperative infection of intraoperative lenses is low (0.10–0.30%), the infection usually is serious and results in endophthalmitis and permanent loss of vision.^{240,270} The predisposing factor for infection is bacterial adhesion to intraocular lenses during insertion. After adhesion is accomplished, the bacteria replicate, congregate, and form multiple layers of microcolonies that represent a biofilm in which the bacteria are embedded in a layer of slime. The major pathogens associated with this infection are *S. aureus* and *S. epidermidis*, which account for 90% of all isolates, although α -hemolytic *Streptococcus* spp. especially *Streptococcus pneumoniae*,⁴¹⁹ gram-negative bacilli, *Pseudomonas*, fungi,³⁶⁴ *Chlamydia trachomatis*, *Nocardia* spp., and rapidly growing mycobacteria are isolated on occasion.^{12,126,270,330,383,396,467,586} Intraocular lens-associated endophthalmitis is a serious infection that is difficult to diagnose and treat.^{37,423,510,527,567} In a few cases, use of topical and systemic antibiotics alone has been successful in eradicating the infection, but in most cases surgical debridement and systemic antibiotics are required for cure. Empirical therapy for these infections consists of an extended-spectrum, penicillinase-resistant penicillin, a second-generation cephalosporin,

or, in some instances, clindamycin or vancomycin. In cases of fungal endophthalmitis, treatment with the later-generation azoles alone and in combination with an echinocandin has been shown to have clinical success.¹²⁶ In rapidly growing mycobacterial endophthalmitis combinations of topical and intravenous antibiotics to which the organism is susceptible have been used for treatment.³³⁰

Contact Lenses

Primarily three different types of contact lenses are available. Hard lenses are made of PMMA, a substance that is impermeable to water and gas. This type of lens is designed to be worn only during waking hours because it limits oxygen flow to the cornea to that present in tears. Gas-permeable hard lenses are composed of silicone, cellulose acetate butyrate, or PMMA-silicone copolymers; they allow gas but not fluid to pass through the lens. Hydrophilic or soft lenses are made of a cross-linked hydrogel polymer or copolymer and consist of 38% to 85% water by weight; these lenses are permeable to both gas and water and allow the user to wear them continuously. However, for all these types of lenses, infection may result in damage to the corneal epithelium.

The two main infections that occur in association with contact lenses are conjunctivitis and keratitis.^{81,257} The causative bacteria seen most commonly with these infections are *S. aureus*, streptococci, *Pseudomonas* spp. (found in improperly stored cleansing solutions), and fungi (including *Candida* spp., *Alternaria*, *Paecilomyces*, *Fusarium*, *Curvularia*, and other filamentous fungi, and *Acremonium*). Improper cleaning of soft or hydrophilic lenses may cause them to become a source of infection when bacteria penetrate the lens matrix. Risk factors for fungal keratitis include use of contaminated contact lens solution, trauma, contact lens wear, ocular surface disease, systemic diseases affecting the immune system, diabetes, use of systemic steroids, and recent chemotherapy.^{9,83,535,588} Fungal keratitis frequently is a severe disease in which diagnosis may be difficult, response to medical therapy is generally slow, and the clinical outcome may be poor. Corneal perforation is 5 to 6 times more likely with fungal keratitis than in bacterial keratitis.⁵⁸¹ In a retrospective multicenter case series of 733 cases of fungal keratitis that looked at the epidemiology and microbiologic characteristics of fungal keratitis at tertiary eye care centers in the United States, it was found that filamentous fungi were more commonly found as the cause of keratitis among refractive contact lens wearers whereas yeasts, especially *Candida* spp., were the most common causative organisms in patients with ocular surface disease and ocular trauma.^{249,587} Treatment of keratitis usually consists of removal of the lens and application of topical antibiotics or antifungals. The most commonly used topical antifungal regimen is a combination of natamycin 5% and amphotericin B 0.15%. Twenty-five percent of patients also may require systemic antifungal therapy in addition to the topical therapy. In fungal keratitis, 16% to 26% of patients require surgical intervention with therapeutic keratoplasty in addition to medical therapy.^{227,249} To prevent the development of infections associated with contact lenses, users should adhere strictly to the manufacturer's suggested guidelines for wearing and cleaning the lenses.

A rare and often devastating infection associated with the use of contact lenses is infection with the fresh-water protozoan *Acanthamoeba*.^{98,201,357,500} This organism contaminates the lens when sterility of the cleansing solutions is not maintained; it has been associated with users who prepare their own solutions and use of contaminated contact lens disinfection solution.^{110,544,590} *Acanthamoeba* is very difficult to eradicate because it is not susceptible to standard antiparasitic agents, and it produces a chronic keratitis that can be complicated by corneal perforation and loss of the eye. Corneal transplantation may be necessary in many cases to restore vision.^{201,500} In a study by Kaiserman and colleagues to assess the prognostic factors influencing visual prognosis and length of treatment after acanthamoeba keratitis, infection acquired by swimming or related to contact lenses, having neuritis and pseudodendrites, the absence of an epithelial defect, having been treated with chlorhexidine, and not having received steroids were factors that were associated with better final best spectacle-corrected visual acuity (BCVA); having an epithelial defect on presentation and having been treated with topical steroid were associated with worse BCVA.²³⁹

FIG. 74.1 Left ventricular assist device (LVAD). (Modified from Fisher SA, Trenholme GM, Costanzo MR, Piccione W. Infectious complications in left ventricular assist device recipients. *Clin Infect Dis*. 1997;24:18–23.)

LEFT VENTRICULAR ASSIST DEVICES

The development plus use of mechanical circulatory assist devices has grown very rapidly in the past several decades, especially with the shortage of available donor hearts. Such devices have improved considerably the hemodynamic status and quality of life of patients with heart failure who are awaiting cardiac transplantation. Fig. 74.1 shows a left ventricular assist device (LVAD), a pneumatically driven pump located outside the heart that draws blood from an inflow cannula in the left ventricular apex and ejects the blood through an outlet into the ascending aorta. Within the pump are several sections of Dacron graft material and two trileaflet porcine valves in the inflow and outflow positions to ensure that blood flow is unidirectional. The pump is encased in titanium and implanted via an extended median sternotomy into the left rectus sheath. A percutaneous driveline connects to an exterior power pack for venting or for pneumatic actuation and exits the body after passing through a subcutaneous tunnel, in the left lower quadrant. The interior surface of the pump is textured to prevent the formation of thrombi and encourage the deposition of a biologic pseudointimal lining. Most LVADs are surgically implanted through a median sternotomy, with pump placement primarily in the intraabdominal or preperitoneal space. Ventricular assist device designs primarily fall into two major categories: pulsatile and continuous flow devices. Pulsatile devices are first-generation devices that were designed to mimic nature by providing pulsatile circulation; they have many moving parts, including a diaphragm to hold and eject blood, valves to maintain directionality, and an air vent and conduit for cooling of the working parts. These requirements have limited the durability and size of these devices. Because of the multiple moving parts, these devices begin to wear out within the first 2 years of use, and the large size necessitates placement in the preperitoneal space or intraperitoneal space. The second-generation continuous flow devices are smaller and have fewer moving parts. These devices primarily consist of inflow and outflow pumps and a rotor, with a smaller conduit to the power source that does not include an air vent. Since January 2010, 98% of LVADs implanted are of continuous flow design.²⁵⁹ Once the device is implanted, in most cases it cannot be removed without performing concurrent cardiac transplantation.^{197,248,334,336,381}

Infection of an LVAD can involve any portion of the LVAD, including the surgical site, driveline, pocket, and pump. Infections occur most commonly within the first 3 months of device implantation, with the risk for severe infection and sepsis peaking at 1 month. The cumulative risk for device infection increases the longer the device remains in place; the incidence of infection significantly decreases after 3 months.^{20,76,209,211,245,319,370} Based on data from the Interagency Registry for Mechanical Circulatory Support (INTERMACS), overall infection rates were 17.5 infections per 100 patient-months during the first 12 months after implantation.^{260,480,498} The rates of infection have been shown to vary among generations of device, with 28.9 infections per 100 months in the pulsatile devices ($n = 406$) and 11.8 infections per 100 months in the continuous flow devices ($n = 548$) ($P < .0001$). It was also found that infection accounted for 16% of deaths associated with LVAD implantation.^{209,259,451,457}

The approach taken by many centers for infection of an LVAD includes both preventive and interventional steps that are instituted before, during, and after implantation. Preventive strategies are focused on prevention of infections related primarily to the driveline and device pocket through the use of clean implantation techniques and limited traffic in the operating room in which the procedure is being performed. Antibiotic prophylaxis usually is given for 48 hours near the time of implantation of the LVAD and may include intravenous trimethoprim-sulfamethoxazole, rifampin, and fluconazole, along with the application of mupirocin ointment to the nares. Additional preventive measures include soaking the surfaces of the LVAD in vancomycin and gentamicin for 30 minutes before placing it, irrigating the device pocket with povidone-iodine (Betadine), and meticulously placing the subcutaneous tunnel in the appropriate position. Postoperative care with sterile and semisterile dressing changes around the driveline is emphasized.^{24,146,153,209,335,336,400,505,569}

Despite the preventive measures taken, infection, thromboembolism, and hemorrhage at the time of implantation remain the most common complications associated with the use of mechanical circulatory support devices. Of these complications, infection has the most significant impact on morbidity and mortality.¹⁵⁸ Predisposing factors for development of device-related infections in these patients include a variety of host, device, and operative characteristics. Device-related risk factors are correlated with increased size and surface area of the device, turbulence of flow, contact of blood with the prosthetic surfaces, device-related pockets and cavities, transcutaneous drivelines, and power cables.^{365,382} Operative and environmental risk factors include extent of surgery necessary for implantation hemorrhage, reoperation, frequent occurrence of multiple organ dysfunction or failure, duration of mechanical circulatory support, duration of hospitalization and intensive care unit stay, use of indwelling lines and catheters, parenteral nutrition, operative technique, and time.^{299,417} The incidence of infection in patients on LVAD support for longer than 60 days is reported to be two times higher than that in patients with an LVAD in place for less than 30 days; initial episodes of infection after 90 days are rare.^{363,408,476} With regard to patient-related risk factors, the severity of heart failure symptoms and presence of poor health and comorbid conditions, including diabetes, hyperglycemia, obesity, alcohol use, and renal disease, has been associated with increased risk for infection.^{49,172,355,430,476} In addition, some evidence indicates that implantation of an LVAD itself may lead to defects in cellular immunity secondary to an aberrant state of T-cell activation that predisposes LVAD recipients to the development of candidal and other systemic infections.^{19,170,225,258,408} The incidence of infection after implantation of an LVAD is reported to range between 13% and 80%, with most studies documenting an infection rate of 30% to 50%.^{16,146,210,416,479,560} Most series report that the device pocket and drivelines are the device-related sites that account for most of the infections. Placement of the LVAD in the abdominal cavity instead of the preperitoneal area has been shown to decrease the chance for development of infection.³⁶³

Driveline infections are thought to result from a lack of integration of tissue around the driveline that allows the driveline to move and irritate surrounding tissues, which can result in an infection in the exit site and, in some cases, bacteremia. Such infections generally are defined by pain, erythema, warmth, drainage, or purulent discharge at the

driveline exit site in the presence of a positive culture.²⁹³ Bacteremia developing after implantation of a pump and infections of the pump itself are additional reported complications.^{24,335} In a study of 205 patients who underwent placement of LVADs at the Cleveland Clinic, positive blood cultures were noted in 52%, infections of the driveline site occurred in 22%, and infections of the pump pocket developed in 9.2%.²⁴⁸ Sun and colleagues⁵⁰⁵ reported their experience with 95 patients who underwent insertion of an LVAD. Twenty-six (27%) of these patients experienced device-related infections involving the driveline, device pocket, or blood-contacting surfaces; 15 (57.7%) of the 26 had infections of the driveline site. Persistent bacteremia and progression of infection of the device pocket and driveline site can lead to the serious infection of LVAD endocarditis, which mimics prosthetic valve endocarditis, is very difficult to treat, and is associated with a high mortality rate. LVAD endocarditis is defined as positive cultures of the LVAD surface in conjunction with clinical signs and symptoms of infection during LVAD support. Manifestations of this condition are varied and range from persistent fever and bacteremia or fungemia to cerebral thromboembolism, LVAD inlet obstruction with hemorrhage, or LVAD outflow graft rupture.²⁴ In a report by Weyland and associates⁵⁶⁹ of 27 patients who underwent insertion of LVADs, infections of the driveline developed in 8 (30%) of the 27 recipients, and LVAD endocarditis, defined as positive cultures from the pump chamber, was found in 12 (44%) of the patients; 8 (67%) of the 12 died of endocarditis.

Despite a high potential for the development of serious morbidity after placement of an LVAD, studies have shown that the presence of an infection after insertion of an LVAD does not seem to have very much influence on eventual cardiac transplantation and posttransplant outcome. A study by Argenziano found that infection subsequently developed in 29 (48%) of 60 patients who underwent insertion of an LVAD.²⁴ The most frequent sites of infection were the blood (27%), LVAD driveline (13%), LVAD surface (13%), and central venous catheter (10%); these sites thus represented 63% of all infections. The overall mortality rate, the rate of successful cardiac transplantation, and the rate of infection after transplantation were not influenced by the presence of infection during LVAD support.²⁴ In another study, Sinha and colleagues⁴⁷⁹ reviewed their experience with 86 patients who received LVADs; device-related infections developed in six patients, five (83%) of whom had infections of the pocket. This study also found that the presence of infection during LVAD support did not influence successful cardiac transplantation or patient survival after transplantation. Over a 6-year period, Schulman and colleagues⁴⁵⁸ reviewed their experience with 149 patients who received LVADs as a bridge to heart transplantation and sought to determine the impact of device-related infections on posttransplant survival and posttransplant infection. Of the 149 patients, 110 were successfully bridged to cardiac transplantation. Pretransplant device-related infections (e.g., pocket infections, wound infections, and postimplant bacteremia) had no negative effect on bridging to transplantation. However, patients with pretransplant sepsis were less often successfully bridged to cardiac transplantation. The presence of a pretransplant device-related infection was found to have no effect on posttransplant 1-year survival rates, although it was associated with an increased rate of posttransplant infection, especially if the patient had a driveline infection during LVAD support. Specifically having a driveline infection during LVAD support predisposed for having an infection in the former LVAD pocket or driveline site after cardiac transplantation, but did not predispose to having sternal wound infections, bacteremia, or sepsis in the posttransplant period. Diagnosing an infection early, determining the location and the extent of the infection, and assessing therapeutic efficacy can be a challenge in patients with LVADs. Anatomic imaging modalities such as CT and MRI may have limited value because of the presence of metallic CT artifacts and contraindications to using MRI. New imaging modalities, such as radiolabeled leukocyte single-photon emission computed tomography (SPECT/CT), are being studied to assess the accuracy of these modalities in revealing both anatomic location and extent of infection in patients with an LVAD. Preliminary results of leukocyte SPECT/CT have shown it to be very accurate in diagnosing an LVAD-related infection.^{72,294,300}

Microbiology of Left Ventricular Assist Device Infections

Numerous organisms have been isolated from LVAD infections. In most series, *S. aureus* (including methicillin-resistant strains), *S. epidermidis* and other coagulase-negative staphylococci, and *Enterococcus* spp. are the organisms most commonly isolated from these infections, usually within the first 4 weeks after implantation. Other organisms such as *Enterobacter* spp., *P. aeruginosa*, *Serratia marcescens*, *Klebsiella* spp., *Stenotrophomonas maltophilia*, *Citrobacter koseri*, other gram-negative organisms, and polymicrobial organisms were seen more commonly later in the clinical course.* Fungal infections (e.g., *Candida albicans*, *Candida parapsilosis*, *Aspergillus* spp., and *Mucor* spp.) have been reported or observed as well and were responsible for approximately 16% of the infections.^{33,116,121,210,333,389,471} However, colonization with fungi occurs in 35% to 39% of patients with LVADs.¹⁷⁰ Investigators suggested that treatment with broad-spectrum antibiotics (common in these patients) rendered them more susceptible to the development of fungal infection. When a fungal LVAD infection is suspected, signs of thrush, cutaneous rashes, esophagitis, retinal changes, peripheral embolization, and unexplained decrease in LVAD output should be investigated. The presence of yeast on Gram stain of the fluid surrounding the device and ultrasound showing increasing amounts of fluid around the device can be used to help confirm the diagnosis.¹⁷⁰

Management of these infections, especially LVAD endocarditis, presents a major challenge, given that the device usually cannot be removed unless simultaneous heart transplantation is performed; moreover if transplantation is accomplished, multiple issues regarding the immunosuppressed condition of the patient are raised. In most cases, management involves a prolonged course (i.e., usually 4 to 6 weeks) of aggressive antimicrobial or antifungal therapy (or both) appropriate for the organism or organisms isolated, with meticulous attention given to skin care around the driveline exit site; debridement, drainage, surgical revision, and irrigation with povidone-iodine of infected wound sites; or, in certain instances, replacement of the LVAD unit or cardiac transplantation before completing antibiotic therapy if a donor heart becomes available and all blood culture results are negative.^{146,210,335}

EXTRACORPOREAL MEMBRANE OXYGENATION CIRCUITS

Extracorporeal membrane oxygenation (ECMO) is a life support device used most commonly for treating severe cardiac and pulmonary failure in neonates and children. Patients undergoing repair for congenital cardiac lesions may require ECMO support (>1%). In addition a growing number of children are receiving ECMO support for acute decompensation from myocarditis; cardiomyopathy; post-cardiac arrest; acute respiratory distress syndrome; severe bacterial, viral, or aspiration pneumonia; and sepsis with hypotension thought to be due to cardiac output failure.^{316,347,422,517} Specific indications for neonates include meconium aspiration syndrome, congenital diaphragmatic hernia, persistent pulmonary hypertension, and others.⁵²¹ Although the overall survival rate of children managed by ECMO has improved in recent years, it still is approximately 50% to 80%, and is lower in adults.^{38,422,521,562,574} Multiple cardiac and noncardiac factors are associated with increased morbidity and mortality rates. Patients with a single ventricle or residual cardiac defect after surgery have a less favorable ECMO outcome.^{52,107,266} Renal dysfunction, especially requiring hemodialysis, multiple organ system failure, initiation of ECMO in the operating room, blood product transfusion, mediastinal bleeding, ECMO circuit problems, and duration of ECMO for longer than 10 days also were predictors of increased risk for mortality.^{3,266,356} The infection rate for patients on ECMO ranges from 6% to more than 40%, with a relatively recent report of 10.2% in about 40,000 patients in the Extracorporeal Life Support Organization registry.⁵⁵⁵ Recent reports suggested a higher infection rate in older patients with culture-proven infections, at 6.1% to 10.1% in neonatal patients, 14% to 23% in pediatric patients, and 20.5% to 30.6% in adults.^{51,460,574} The rate of development of sepsis in neonates while on

*References 24, 121, 146, 173, 210, 333, 335, 479, 522, 569.

ECMO in one study was 4.2% and was associated with higher complications and mortality.³⁴⁸ Multiple risk factors for acquiring infection while on ECMO were identified, including indwelling vascular or urinary catheters,³⁵⁶ duration of ECMO bypass (>10 days),^{220,501} procedures before or during ECMO,³⁷⁷ ECMO complications,⁶⁸ and changes in the humoral and cellular immunity.⁵³⁹ Patients with infections usually will need longer bypass support³⁷⁷ and will have a delay in post-ECMO lung recovery and increased mortality.^{51,272,356} In one study, mediastinitis occurred in 11% of adults, with cardiac surgery noted to be a risk factor for this infection.⁵¹⁷

Earlier reports suggested that gram-positive cocci (e.g., *S. aureus* and coagulase-negative staphylococci) are the most common etiologic agents and are still frequent pathogens.⁵⁰¹ However, gram-negative bacteria (both lactose fermenting and non-lactose fermenting²²⁰) and fungi¹⁹⁹ are becoming more commonly reported. *Candida* spp. were found to be frequently isolated pathogens in children and adults.^{51,409,506} The distribution of these pathogens is similar to their distribution in other patients with infections treated in the intensive care unit.¹⁹⁹ The signs and symptoms of infection often are subtle and nonspecific. Fever develops in only half of these patients. The value of tachycardia and elevated cardiac output also is limited because these patients frequently are tachycardic, with increased cardiac output caused by a systemic inflammatory response (e.g., complement; cytokines such as TNF, interleukin-1 [IL-1], and IL-6; and acute phase reactants such as C-reactive protein and procalcitonin), which is characteristic of cardiopulmonary bypass procedures.^{71,352,409,501,506} For the same reason, leukocytosis (unless developing acutely) and an elevated erythrocyte sedimentation rate (ESR) should be interpreted with caution. In addition, physical examination and radiologic tests may be difficult to interpret.⁷¹ Consequently a high index of suspicion with careful evaluation of potential infection source (e.g., surgical wound and insertion site of catheter) and surveillance of blood and urine cultures is needed to identify these infections.

Most patients undergoing ECMO are treated with multiple broad-spectrum antibiotics. This practice probably is one of the reasons for the increased incidence of multidrug-resistant, gram-positive (e.g., *Enterococcus*) and gram-negative bacteria, as well as fungal (e.g., *Candida*) infections. In addition, many of these patients will be colonized with these same bacteria. Therefore if a deep bronchial suction or urine culture (performed routinely) becomes positive but without supporting evidence of infection (e.g., increased white blood cell [WBC] count, fever), serious effort to distinguish between colonization and infection should be made before initiating an unnecessary change in antimicrobial therapy. If a decision to treat is made, appropriate coverage for both gram-positive and gram-negative organisms should be chosen. If blood, urine, and bronchial cultures remain negative and the patient's condition is not improving or the culture becomes positive for a fungus, antifungal therapy should be added.

Most ECMO centers administer antibiotic prophylaxis; however, the optimal spectrum and duration of this practice are unknown. Some studies suggested that use of prophylaxis (for 24 hours before the ECMO is started) was effective in reducing infections^{69,501}; others found no correlation between antibiotic prophylaxis and reduction in infection rate.²²⁰ Of interest, despite advances in critical care for ECMO patients (including antibiotic prophylaxis), no significant decrease has occurred in infection rate during the past two decades.⁶⁸ The lack of specific guidelines and evidence from randomized trials evaluating different durations and spectrums of antibiotic contribute to the confusion and controversy in this area.²⁴⁴ If prophylaxis is considered, antifungal prophylaxis (e.g., fluconazole) should be added because it was shown to decrease the incidence of fungal infections, which are increasing.¹⁶¹

PERMANENT CARDIAC PACEMAKER AND IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR INFECTIONS

Permanent Cardiac Pacemaker Infections

Cardiac pacemakers have been widely used since the 1980s and the American Heart Association (AHA) has recently expanded the indications

for their use.¹³⁴ Two types of permanent pacemaker generators are in use; those with transvenous electrodes and those with epicardial electrodes. Both types are implanted in either the chest or the abdominal wall; pacemakers with epicardial electrodes are the ones more commonly used in the pediatric population. Studies are currently being conducted on the next generation of pacemakers, which are miniaturized, fully self-contained leadless devices that are nonsurgically implanted in the right ventricle with the use of a catheter.⁴³²

Infection is one of the most common medical complications of implantation of permanent pacemakers, with reported rates ranging from 0.2% to 5.8% and a high mortality rate.^{74,90,557} An estimated 25% of cardiac pacemaker-associated infections develop within 1 to 2 months of placement of the device, but delays of up to 12 months may occur before diagnosis is established. Several studies suggested that the relative rate of infection associated with permanent pacemakers has increased despite improved surgical techniques and better design of the devices themselves,^{74,538,557} but a recent study demonstrated a fairly constant rate of infection over the course of 20 years.²³⁵ Studies have shown that infections of permanent cardiac pacemakers seem to occur more commonly in patients with both local and systemic underlying medical problems, especially diabetes mellitus or an underlying renal insufficiency, or in those who are undergoing treatment with corticosteroids, anticoagulants, or other types of immunosuppressive therapy.^{53,412,484,557} Other well-characterized independent risk factors include surgery related to any part of the pacemaker (especially replacement of a battery or upgrade of the pacemaker),^{80,191,200,235,278,369} the presence of a hematoma after implantation,^{75,369,483} temporary transvenous pacing,²⁰⁰ and epicardial leads.⁴⁸³ Multiple (two or more) pacemaker insertions and physician inexperience with insertion also represent significant risks for development of infection.^{191,369} The presence of a central venous line also increases the risk for systemic infection.⁸⁰ Multivariable analysis of the largest reported pediatric pacemaker infections identified only presence of Down syndrome and manipulations of the pacing system during revisions as risk factors.⁹⁹

Infections of permanent cardiac pacemakers are subdivided into groups depending on the specific site of involvement and whether they are early infections (<1 to 2 months after implantation) or late infections (>2 months after implantation). The groups are (1) local inflammation, infection, and the formation of an abscess in the generator pocket or subcutaneous portion of the lead, or in both sites; (2) secondary infection involving either the generator or the electrodes (including pacemaker endocarditis)^{75,129}; (3) fever plus associated bacteremia, with or without concomitant infective endocarditis, in a patient without any apparent focus of infection¹²⁹; and (4) mediastinitis, pericarditis, bronchopleural cutaneous fistulas, and mixed infections.¹²⁹

The generator pocket and the subcutaneous portions of the leads (i.e., transvenous and epicardial) are the most common sites of infection. Infections of the pocket often are difficult to diagnose and may develop at any time after implantation; however, most tend to develop early and frequently are the result of contamination by skin flora at the time of the procedure.³⁵³ Late infection usually occurs as a consequence of erosion of the device through the subcutaneous tissue and skin. The infection may remain localized to the pocket or may spread to the adjacent electrodes and lead to the development of bacteremia. Infection of transvenous pacemaker leads may occur in as many as 17% of patients who receive permanent pacemakers. These infections often are not apparent initially but have been associated with significant morbidity and mortality.¹⁸³ Infection generally develops along the subcutaneous portion of the leads and, if unrecognized, may progress centrally and result in sustained bacteremia, endocarditis, or both. Infections of the leads tend to occur later than infections of the pocket, with the median time of occurrence being 7 to 8 months after implantation of the pacemaker. Endocarditis as a complication of unrecognized infected transvenous leads can develop years (2 to 3 years) after placement of the pacemaker. Infections of permanent epicardial leads generally occur as a complication of infections of the generator pocket, skin erosion, or direct contamination at the time of placement. However, in contrast to infections of the transvenous leads, infections of the epicardial leads usually result in only local symptoms; rarely they may lead to more severe disseminated disease such as pericarditis, mediastinitis, bronchopleural cutaneous fistulas, bacteremia, or sepsis.

Microbiology

Staphylococci (*S. aureus* and coagulase-negative staphylococci) are the most common causes of pacemaker-related infections, accounting for more than 85% of such infections; however, a wide variety of organisms have been isolated.^{75,80,328,369,483,486,549} An increasing number of the isolated staphylococci are methicillin resistant. Other gram-positive organisms such as viridans streptococci, other streptococci, enterococci, *Listeria*, and *Corynebacteria* have been isolated as well, but each causes fewer than 1% of cases. Gram-negative organisms such as *E. coli*, *Proteus*, *Enterobacter cloacae*, *P. aeruginosa*, *Klebsiella*, *S. marcescens*, and *Sphingomonas paucimobilis*⁴⁶⁹ are isolated from 5% to 20% of device-related infections. In addition, *Candida*, *Aspergillus*, *Pseudallescheria*, *Trichosporon* spp.,⁴²⁵ and other fungi have been isolated rarely, as well as *Mycobacterium* spp.; however, infections with these organisms generally are associated with poor clinical outcomes.*

Clinical and Laboratory Findings

Diagnosing a pacemaker-associated infection can be difficult because of its nonspecific symptomatology, and months may elapse after the onset of symptoms before the diagnosis is established. Symptoms may be confined to a local area or may be more widespread, with the development of bacteremia or other systemic effects. Rarely the only sign of infection is persistent pain at the pocket site.²⁶⁵ Fever (84–100%) and chills (75–84%) are considered the most common systemic symptoms and are indicators of local infection, especially if they occur after the second postoperative day in association with other signs; however, they may be the only clinical manifestation in more than a third of patients.^{75,264,354,375,573} Early infections are more likely to be accompanied by both local and systemic clinical findings and are manifested more commonly as infections of the generator pocket, bacteremia, or septicemia^{75,311,597}; late infections, on the other hand, typically cause vague symptoms that evolve over the course of time and usually are lead-related infections and endocarditis.^{278,549}

Infections of the generator pocket typically cause local swelling (21%), erythema (34%), pain (32%), drainage (through an incompletely healed incision or fistulous tract) over or adjacent to the generator pocket (25%), and warmth (11.5%).⁹⁰ Sterile breakdown of the pacemaker pocket develops in an estimated 5% of patients with permanent pacemakers, and skin or soft tissue erosion over the electrodes occurs in an additional 2% to 4%. Because these complications are associated with a high risk for the subsequent development of infections, the presence of any erosion is considered a potential indicator of device-related infection, especially if the erosion occurs more than 24 months after placement of the pacemaker, at which time the infection rate may be as high as 80%.^{48,182} Pacemaker-related endocarditis is a relatively rare complication that occurs in 0.05% to 0.5% of cases after implantation of a pacemaker. Such endocarditis is associated with a mortality rate as high as 34% in some series.^{75,157,264} It tends to be a late complication; only 27% to 36% of patients are seen within 6 to 12 weeks after the last procedure at the pacemaker implant site, with symptoms developing in most patients a mean of 25 months after the last procedure at the implant site. The diagnosis of pacemaker-related endocarditis is difficult to establish, and usually a delay occurs in making the diagnosis, with a mean interval of 5 to 8 months after the onset of symptoms.^{75,264} Pulmonary symptoms are found in 20% to 45% of patients with pacemaker-related infections and may consist of bronchitis, lung abscess, pneumonia, or pulmonary embolism; these symptoms are seen more commonly in late-onset infection and in patients with intravenous lead-related infection.^{75,264}

A variety of laboratory and imaging studies may be performed to aid in establishing the diagnosis of a pacemaker-related infection. A recent update from the AHA suggested two sets of cultures from blood, generator pocket site, and lead tips when infection is suspected.³² A prospective study that looked at patients with pocket infections of cardiovascular implantable electronic devices found that sonication of generators and leads that were surgically removed was more sensitive than swab cultures or blood cultures alone in detecting bacteria in these types of infections.⁴³⁶ An elevated ESR is found in 82% to 97% of

patients, and peripheral leukocytosis is seen in 50% to 66%. The presence of a collection of fluid around the device as seen on ultrasound is suggestive of device-related infection. Gallium scanning may be performed in an attempt to determine the nature of the fluid (i.e., inflammatory vs. infectious). Transesophageal echocardiography (TEE) can be helpful in identifying endocarditis (especially when blood culture results are negative). TEE has emerged as a major tool in diagnosis; studies have shown that this test was able to demonstrate vegetations and other lesions on the electrodes, ventricular endocardium, and tricuspid valve in 90% to 96% of patients with pacemaker-related infections.^{75,264,549} Only the combination of negative TEE and ECHO should be used to rule out endocarditis.⁴⁸⁶

Management and Treatment of Infection

Appropriate therapy for pacemaker-related infections is tailored to the specific clinical situation and depends on several factors: (1) whether the infection is limited to the generator pocket or subcutaneous electrodes, without bacteremia; (2) whether bacteremic pacemaker-related endocarditis is present with or without involvement of the subcutaneous electrodes; and (3) what organism is involved.

If the infection is limited to the generator pocket or subcutaneous electrodes, optimal treatment consists of both medical and surgical intervention in which all of the parts of the infected device are removed. Studies have shown that failure to remove completely all portions of the infected device results not only in failure to cure the infection but also in higher mortality rates.^{32,75,556} In addition, infection relapse is higher.^{90,324,484} The patient is given parenteral antimicrobial therapy, and an exchange of the pacing system with total removal of the infected device and simultaneous insertion of a new pacemaker at a different site is performed surgically. The infected subcutaneous pocket is drained, debrided, and packed open, and local wound care is instituted. Initial antibiotic therapy should provide coverage for both staphylococci and gram-negative bacteria; therapy is tailored once the organism is identified and its antibiotic susceptibility is known. Initial regimens include vancomycin plus an aminoglycoside. Oxacillin or nafcillin plus an aminoglycoside may be used if MRSA is rare in the community. In certain instances, a new pacemaker cannot be placed at the time of removal of the infected device; in such situations, a period of temporary transvenous pacing is instituted until a new pacemaker can be implanted. For local pocket infections, antimicrobial therapy targeted at the causative organism should be administered for 10 to 14 days.

The consensus approach to the management of pacemaker-related endocarditis and bacteremia involves removal of both the generator unit and the electrodes in conjunction with prolonged administration of parenteral antibiotic therapy designed to treat endocarditis (usual duration, 4 weeks).^{32,484} In cases of MRSA, duration of treatment should be extended to 6 weeks.³⁰¹ A longer duration may be considered in patients with other sites of infection (e.g., osteomyelitis or septic thrombophlebitis). Vancomycin should be the initial antimicrobial treatment of choice before the etiologic agent is identified because the majority of infections are due to staphylococci species. More specific antibiotic regimens can be used when the pathogen is identified and in vitro susceptibility is available. Mortality rates may be as high as 50% for patients in whom total removal of the pacemaker unit is not performed.^{75,264,399} Percutaneous removal of electrodes that have lead-associated vegetations smaller than 20 mm is acceptable,^{32,145} but extraction of the electrodes with vegetations larger than 20 mm may be difficult and risky to perform, and surgical removal by cardiectomy may be necessary.³² In patients who require a pacemaker, temporary transvenous pacing may be implemented until a new permanent pacemaker can be placed. Sterility of blood cultures should be ensured before a new pacemaker generator and electrode are placed.

Infection of Implantable Cardioverter-Defibrillators

The first implantable cardioverter-defibrillator (ICD) was placed in 1980, and, during the past several decades, the device has become a successful therapeutic modality for treatment of patients (both adults and children) with life-threatening ventricular arrhythmias. Older devices required surgical placement of a pulse generator, extrapericardial or epicardial defibrillation patches, and a transvenous rate-sensing

*References 11, 75, 86, 89, 246, 277, 283, 320, 486, 549, 573.

electrode. More recent systems use transvenous approaches for placement of leads and a subcutaneous or submuscular pulse generator or newer methods of complete subcutaneous ICDs, including subcutaneous leads.^{58,250,403,494,568,575}

Infection is the most serious complication of placement of an ICD.^{75,280} Infection rate ranges associated with placement of ICDs were previously from 1% to 7%.^{495,526} However, infection rates have decreased substantially with the advent of transvenous non–thoracotomy-placed systems, with rates ranging from 0.2% to 1.8%³⁴⁴ and 3.1 per 1000 patient years.¹⁶⁹ Subcutaneous ICDs appear to have lower rates of infection, particularly endocarditis.⁴⁰³ Results from some studies still suggest that ICDs are associated with a greater risk of infection than are permanent pacemakers.⁵⁵⁷ Cost associated with hospital admission, length of stay, and mortality are substantially increased in patients with infection in contrast to those without it.^{482,485,538} Several risk factors that have been identified as increasing the likelihood for development of infection include steroid use, diabetes, heart failure, renal failure, malignancy, chronic obstructive pulmonary disease, skin disorders, anticoagulant drug use, preprocedural fever, and previous device infection.^{53,268} Previous generator replacement, abdominal implantation, postoperative hematoma, procedural duration, and surgeon experience also were reported as contributing to increased risk for infection.^{53,289,537} Abnormal renal function is the most consistently identified risk factor for mortality. Mortality is high, ranging from 24.5% to 29%,^{29,178,181} and is higher for patients with infective endocarditis or bloodstream infection compared to generator pocket infection only.⁵⁵⁰

Most ICD-related infections are clinically apparent within 3 to 6 months after placement, with infections of the generator pocket, subcutaneous patch wound site, epicardial patches, or bacteremia and endocarditis being the most common manifestations. Some infections can be indolent, and only a high index of suspicion will initiate an investigation. An increased WBC count and ESR, anemia, and microscopic hematuria are the most common laboratory findings. As with pacemaker infections, TEE is an effective test to exclude endocarditis because transthoracic echocardiography is helpful in only half of the cases.¹⁵¹ Infection of the generator pocket or subcutaneous patch wound site usually causes local findings of pain, erythema, and collection and drainage of fluid. Occasionally these patients also may be bacteremic or hypotensive. In contrast, infection of the epicardial patches generally results in more systemic symptoms, bacteremia, or pericarditis.³⁷⁹ At least two blood cultures should be obtained to rule out bacteremia. Cultures of the generator pocket and lead tips after removal of the device are essential for identifying the pathogen. Sonication of the extracted device increases the yield of positive cultures.³²⁷

Microbiology

Gram-positive bacteria, primarily coagulase-negative streptococci and *S. aureus* are the major pathogens seen with ICD-related infections and account for 68% to 93% of cases.*

However, a broad spectrum of other gram-positive, gram-negative, and fungal organisms, including *Enterococcus* spp., *P. aeruginosa*, *Corynebacterium*, streptococci, *E. coli*, *Klebsiella*, *Bacteroides fragilis*, *Propionibacterium acnes*, atypical mycobacteria, and *Candida* spp., have been isolated from ICD-related infections. Fungal infection is uncommon, reported in fewer than 2% of patients. Reported rates of polymicrobial infection range from 2% to 24.5%, and many patients with clinical infection are found to have negative cultures (12–49%).

Management

The same approach previously described for pacemaker infection should be applied to ICD infection. To eliminate ICD-related infections effectively, optimal management involves a combination of medical and surgical interventions, especially if the patient is bacteremic or has systemic findings or if the causative organism is *S. aureus*. Several studies have suggested that conservative management (i.e., antibiotic therapy without removal of the hardware) may be sufficient, but others have identified medical therapy as a risk factor for death. A medical management approach should be tried only in cases with superficial or incisional infection and in rare occasions when only the generator pocket is infected

or in patients whose condition prevents removal of the entire device. In these cases, the treatment should consist of administration of parenteral antibiotics, wound care, and removal of only the generator portion of the device, with implantation of another generator at a different site.^{379,533} The optimal management of any other ICD-related infection is parenteral antibiotics and complete removal of the entire ICD system, followed by reimplantation (after the infection is eradicated) at another site.^{90,280,448,576} Although there are no clinical trial data to define the optimal duration of antimicrobial therapy, at least 2 weeks should be considered after hardware removal, and, if blood cultures continue to be positive 24 hours after removal of the ICD, a longer period (e.g., 4 weeks) should be considered. For infections limited to the pocket site, 7 to 10 days of appropriate antibiotics may be sufficient, with an oral agent being a reasonable option if there is only superficial or incisional involvement.³²

PROSTHETIC JOINT AND ORTHOPEDIC IMPLANT INFECTIONS

The implantation of prosthetic joints along with the use of other implantable orthopedic devices (e.g., pins, screws, plates, rods, external fixators, or Ilizarov apparatus) has improved quality of life greatly and restored function to patients suffering from debilitating bone and joint disease, tumor, or injury. Based on conservative estimates, millions of people worldwide have some form of prosthetic joint or other implantable orthopedic device. Of the possible complications associated with implantation, infection is the second most common cause of prosthetic joint failure.¹⁸ It occurs in 0.6% to 2.4% of total joint replacement¹²⁸ and results in postoperative prosthesis failure, chronic pain, immobility, and, in some cases, loss of the affected limb or, in the worst-case scenario, loss of life.^{5,44,124,500} The health care cost in the United States for treating a single infection of a prosthetic joint is estimated to be more than \$280 million per year nationwide.¹⁹⁶ The number of prosthetic joint infections is increasing.²⁷⁶

Prosthetic joints and implantable orthopedic devices may become infected by two major mechanisms: (1) the prosthetic device may be contaminated by microorganisms at the time of implantation, either as a result of airborne contamination in the operating room or by direct inoculation at the time of surgery; or (2) the prosthetic device may become infected as a result of hematogenous seeding from bacteremia or by direct contiguous spread from an infection adjacent to the prosthesis. Of infections of prosthetic joints, 20% to 40% arise by hematogenous seeding, with the remainder occurring as a result of airborne or direct inoculation.^{4,297,298} Infections may remain asymptomatic for years before symptoms become apparent, and usually a long delay occurs between onset of the infection and the appearance of symptoms and confirmation of the diagnosis. The overall rate of infection of prosthetic joints has been shown to be highest in the first 6 months postoperatively, with a steady decline occurring after this time. The incidence rate for infection of total hip and total knee arthroplasties during the first 2 years postoperatively is reported to be 5.9 infections per 1000 joint-years; in contrast, during postoperative years 2 to 10, it is 2.3 infections per 1000 joint-years.⁴⁹⁹ The risk for acquiring infection and the incidence of infection depend on the anatomic location of the implanted orthopedic device or prosthetic joint, with the hips having the highest risk, followed in descending order by the knees, elbows, shoulders, wrists, and ankles.^{93,424,502} For implantable orthopedic devices, rates of infection range from 2% to 30%.^{317,547}

Risk Factors

Numerous factors have been identified as increasing a patient's risk for developing infection of a prosthetic joint or orthopedic implant, including rheumatoid arthritis, diabetes mellitus, obesity, poor nutritional status, use of steroids, immunocompromised status, psoriasis, hemophilia, sickle-cell hemoglobinopathy, solid-organ transplant, dialysis-dependent renal failure, joint dislocation, and extremes of age.^{44,114,190,387,574} In addition, procedure-related factors such as previous surgery at the site of the prosthesis or implant, extended operation time (>2.5 hours), postoperative bleeding, and hematoma also increase the risk for acquiring an infection.^{114,391,583} The relative risk for the development of

*References 29, 57, 113, 178, 224, 232, 280, 379, 448, 495, 513, 552, 554.

prosthesis-related infections in patients with poor healing and wound complications increases from 13- to 20-fold after total knee replacement and from 22- to 52-fold after total hip replacement.⁵⁸³ In addition, bacteremia from any source increases the risk for prosthesis infection.⁵⁹⁶ For example, prosthesis-related infection developed in 34% of patients with *S. aureus* bacteremia who were followed prospectively.³⁶¹

The implanted metal prosthetic device and the PMMA cement that binds the prosthetic device to adjacent bone also predispose the joint space and bone to infectious processes, given that both are foreign bodies. In vitro studies have shown that the unpolymerized form of PMMA cement predisposes to infection by inhibiting phagocytic, lymphocytic, and complement function; the risk for acquiring infection seems to be enhanced further once the cement has polymerized in the body.^{404,405} Cementless prostheses have been designed in an attempt to overcome the problem of infection associated with the PMMA cement. For certain orthopedic implants, the integrity of the skin is compromised chronically, thus providing ready access to organisms from the external environment.

Microbiology

Although any microorganism can cause prosthetic joint infections, more than half of the infections are caused by *S. aureus* or coagulase-negative staphylococci.^{114,596} Other gram-positive bacteria (e.g., β -hemolytic streptococci, viridans streptococci, and enterococci) cause 20% to 25% of infections. Antibiotic resistance in these organisms is increasing, and multiple strains of staphylococci may be present in a single prosthetic joint infection.^{229,317,449,547,578} Less commonly, aerobic gram-negative bacilli, including *E. coli*, *Proteus mirabilis*, *Klebsiella* spp., *Salmonella* spp., *S. marcescens*, other Enterobacteriaceae, and *P. aeruginosa*, may cause infection. In addition, 4% to 10% of infections are caused by anaerobic organisms such as peptostreptococci and *Bacteroides* spp.; polymicrobial infections occur in approximately 10% of cases, with *S. aureus* and anaerobes the most frequently found.³²³ Infections with fungi, particularly *Candida*, *Aspergillus*, and *Penicillium* spp., or with mycobacteria (i.e., *Mycobacterium tuberculosis*, *Mycobacterium avium* complex [MAC], and other rapidly growing mycobacteria) also have been described.^{31,43,321,531} Rarely a wide spectrum of other organisms, including *Corynebacterium*, *Propionibacterium*, *Bacillus* spp., and *Mycoplasma hominis*, have been reported to cause infection. Zoonotic bacteria such as *Brucella* spp., *Yersinia* spp., and *Pasteurella* spp. rarely can cause infection and should be considered in the correct epidemiologic setting.³²¹ Approximately 10% of infections are culture negative.

Certain clinical situations may predispose a patient to particular organisms as the cause of infection. Pyogenic skin infections commonly result in staphylococcal and streptococcal infections of prosthetic joints, whereas infections of the teeth and gums are frequent causes of viridans streptococcal and anaerobic infections in prostheses. Genitourinary and gastrointestinal tract procedures or infections frequently are associated with enterococcal and gram-negative bacillary infections of prostheses. The increased use of TNF- α blockers in patients with joint prosthesis predisposes them to infections with unusual pathogens (e.g., fungi or mycobacteria).

Clinical Manifestations

The clinical findings and severity of symptoms seen with infections of prosthetic joints are highly variable and determined primarily by three factors: (1) the route of infection—the hematogenous route versus direct inoculation; (2) the virulence of the infecting pathogen—*S. aureus* and, to a lesser extent, β -hemolytic streptococci and gram-negative bacilli seem to be particularly virulent pathogens capable of producing a fulminant clinical picture, whereas infection with organisms such as coagulase-negative streptococci is associated with a more chronic, indolent course; and (3) the nature of the tissue in which the microorganism proliferates—hematomas, seromas, ischemic wounds, and the tissues of diabetic patients and those receiving steroids all enhance the ability of the bacteria to proliferate and spread, thereby promoting the development of a more deep-seated fulminant infection.

The most common initial symptom is joint pain, which occurs in 95% of cases. Such pain can range from an acute fulminant illness with erythema, severe joint pain, swelling (38%), high fever (43%), and

systemic symptoms to a chronic, slowly increasing pain in the joint without typical signs of inflammation that may be associated with the formation of a cutaneous draining sinus (32%) but no systemic symptoms.^{114,596} The presence of constant joint pain is more indicative of infection than is the presence of pain occurring only with movement or weight-bearing, which is more common in aseptic and mechanical complications.

For implantable orthopedic devices, the most common initial symptom of infection is erythema, swelling, pain, or drainage from the area around and adjacent to the implant. Local symptoms also may be associated with fever, especially if the device is extensive or deep seated.

Diagnostic Studies

Laboratory screening tests commonly used to diagnose infection of a prosthetic joint or implanted orthopedic device such as peripheral WBC count, C-reactive protein (CRP), and ESR are neither specific nor sensitive (sensitivity, 60–96%; specificity, 55–92%).^{114,492} Of these tests, CRP seems to be the better test. These test results may be normal, especially in patients with chronic, slowly progressing infection. Several biomarkers (e.g., procalcitonin, TNF, and IL-6^{45,466}) have been suggested as diagnostic tests. Molecular techniques such as polymerase chain reaction (PCR), fluorescence in situ hybridization (FISH), and immunofluorescent microscopy were reported to have a sensitivity of 63% to 100% in detecting bacteria in prosthetic joint infections^{202,325} but were not studied widely.^{13,338}

The principal radiologic studies used for detection of an infected prosthetic joint include plain radiographs, arthrograms or sinograms, and radioisotope scans (indium and technetium diphosphate). Abnormalities that may be suggestive of infection and can be seen on plain radiographs include radiolucency at the bone-cement interface, motion and changes in position of the prosthetic components, evidence of osteomyelitis, cement fractures, and periosteal reaction. Intraarticular injection of dye (arthrogram or sinogram—in the presence of a sinus tract) may demonstrate abnormal communication between the joint space and the bone-cement interface. These radiographic abnormalities are present in approximately 50% of infected prostheses.^{104,314} Nuclear scans with indium-111-labeled WBC or technetium-labeled sulfur colloid (^{99m}Tc) may be used to detect periprosthetic inflammation. Scanning techniques have a sensitivity of 80% to 86% and a specificity of 94% to 100%.^{385,515} Of note, increased uptake can be seen around uninfected prostheses within the first 6 to 12 months after implantation. Therefore positive findings after this time are abnormal and reflect inflammation (which could be due to a variety of causes) but not specifically infection.^{127,206,243,380} Of interest, ^{99m}Tc-labeled ciprofloxacin (which probably binds to live bacteria at the infection site) was shown to be 94% sensitive and 83% specific for diagnosis of chronic infection.⁴⁸⁹ Use of this technique allowed 11 of 12 infections of prosthetic joints to be identified, whereas ^{99m}Tc-WBC scintigraphy was positive in only seven patients.⁴⁹¹ Combining antigranulocyte antibody (^{99m}Tc sulesomab) and ^{99m}Tc colloidal rhenium sulfide (nanocolloids) was shown to be an acceptable alternative.⁴⁹⁰ Positron emission tomography with fludeoxyglucose F-18 (18 FP-FDG PET) was also evaluated as a diagnostic technique.^{114,279,504} CT and MRI are not used routinely in the evaluation of patients with suspected infection of a prosthetic implant because of the large amount of imaging artifact created by prosthetic devices.^{62,351}

Aspiration of joint fluid for culture and culture of tissue obtained intraoperatively are the optimal ways to establish a specific diagnosis of infection of a prosthetic joint. Unfortunately the yield is only 50% to 90%. To optimize the yield, antibiotics should be stopped 2 to 3 days before aspiration or operative cultures are taken.⁵⁹⁶ Although joint fluid findings indicative of an infectious process are a high leukocyte count (consisting mainly of polymorphonuclear leukocytes [PMNs]), a high protein content, and a low glucose concentration, these changes are not specific for bacterial infection and are present in only some patients. Using a cutoff value of 1700 WBC/ μ L with at least 65% PMN cells gave excellent results.⁵²⁴ The fluid obtained should be cultured for a variety of organisms; Gram stain is positive in a third of cases, and a causative pathogen can be identified in only two-thirds of patients.^{399,493} Intraoperative cultures should include, if possible, any purulent discharge, devitalized bone, and tissue from the bone-cement interface. Vortexing,

bath sonication, or both of the explanted prosthesis may increase the yield.³⁹⁴ Histopathologic examination of this tissue usually reveals an infiltration of PMNs consistent with an acute inflammatory reaction but not specific for infection.^{184,525} More rapid, specific, and sensitive tests (e.g., FISH, PCR, immunofluorescent microscopy) are needed to differentiate between noninfectious inflammation and bacterial infection and identify the pathogen in patients already receiving antibiotic or infected with fastidious pathogens.

Treatment

Successful treatment of an infected prosthetic joint involves extensive surgical debridement of all devitalized bone and tissue, removal of the prosthesis and all associated cement, and prolonged parenteral antibiotic therapy.^{36,95} For optimal results, the debridement should be performed within 1 to 3 weeks.^{114,285,322} Microbiologic cure has been found to correlate well with the extent of debridement and the completeness of removal of all residual methylmethacrylate cement. Historically attempts at simple surgical debridement without removal of the prosthetic device in conjunction with parenteral antibiotic therapy had variable success, with relapse rates being as high as 88% by 2 to 4 years after therapy.^{147,454,576} High failure rate was reported in *S. aureus* infections,^{64,551} but in patients with a short duration of prosthetic joint infection caused by penicillin-susceptible streptococci, debridement and antibiotic therapy alone appear to be sufficient, with a low risk for relapse.^{271,343}

Two protocols have been used for the treatment of these infections. A two-stage surgical procedure with prolonged parenteral antibiotic therapy has been shown to be one of the most successful treatment regimens with the best functional results. The first stage involves complete removal of the prosthesis and cement followed by a 6-week regimen of antibiotic therapy empirically chosen to cover the most likely organism and then tailored once the organism has been identified and its antibiotic susceptibility is known. The second stage involves reimplantation of a new prosthetic device at the end of the antibiotic course. Success rates with this procedure range from 87% to 100%.^{144,292} An alternative method of therapy involves a one-stage exchange operation in which the infected prosthetic device and cement are removed, all devitalized tissue and bone are debrided, and a new prosthesis is reimplanted immediately, followed by 6 weeks of parenteral antibiotic therapy. Antibiotic-impregnated (i.e., tobramycin or gentamicin) methylmethacrylate cement is used in these situations, and success rates of more than 75% were reported.^{78,131,132,190,397,428,536,596} This procedure is appropriate only for patients with infections caused by less virulent microorganisms because of the high failure rates seen when a more virulent organism such as *S. aureus* or a gram-negative bacillus is the cause of the infection. The Ilizarov method allows simultaneous treatment of infection, bone and joint deformities, bone loss, and shortening of the limb. This device includes proximal and distal circular external rings with wires passing through the bone and soft tissue from one side of the limb to the other. Although this method is used more often for the treatment of bone nonunion or bone loss with or without infection, David and colleagues¹¹² used this technique successfully to treat 12 patients who failed total knee arthroplasty because of infection. Wound infection and chronic osteomyelitis caused by infection of the wire tract occur infrequently and should be treated by debridement of the infected soft tissue and curettage of the infected bone.

The two-stage prosthetic removal-reimplantation procedure coupled with the incorporation of antibiotic-impregnated cement during reinsertion of the implant, in combination with a 6-week antibiotic regimen, is the mainstay of therapy for infections of prosthetic joints. Selection of antibiotics should take into account the recent increase in methicillin resistance among staphylococci for the following reasons: MRSA infections of the prosthetic joint result in a higher incidence of treatment failure than do infections with methicillin-susceptible *S. aureus*, and the former result in longer durations of hospitalization and a low survival rate free of treatment failure.⁴⁴⁵ Thus vancomycin (with or without rifampin) should be the initial drug of choice for gram-positive bacteria until the susceptibility of the infecting organism is known.⁴⁹¹ In chronic and hematogenous infections (in which gram-negative bacteria are more common) carbapenems, aminoglycosides, or fluoroquinolones should be considered in addition to vancomycin until the microbiology

results are available. Reports of treatment failures (even with vancomycin susceptibility within the treatment range [i.e., 2 to 4/μg per mL])^{219,516} suggest that other antibiotics (e.g., trimethoprim-sulfamethoxazole or linezolid) should be considered. Several reports have shown that linezolid is a reasonable alternative that results in control of the infection.^{346,546}

For infected implanted orthopedic devices, the success of therapy is based on total removal of the device together with parenteral antibiotic therapy. In cases in which the foreign body cannot be removed, extended parenteral antibiotic therapy should be instituted and continued until the device can be removed. The duration of therapy varies with the severity of the infection and ranges from several weeks to several years.

Prevention

Like other surgical procedures, prevention efforts should be focused on reducing the ability of the pathogen to reach the surgical site.¹⁶ Patients should be screened for *S. aureus* colonization, and efforts should be made to decolonize those found to be carriers. The success of intranasal mupirocin or bathing with chlorhexidine in reducing the rate of surgical site infections suggests that such measures should be considered for patients receiving prosthetic joint or other implantable orthopedic devices.^{55,401}

The use of prophylactic antibiotics for dental procedures in patients with an orthopedic device is controversial. Although no evidence supports such prophylaxis,⁴⁶ the American Academy of Orthopedic Surgery recommended it for all patients with joint implants.¹⁴ The practice of using antimicrobial-loaded bone cements for prophylaxis is also controversial. Retrospective studies found it to be effective, but prospective studies found no extra benefit compared to systemic antibiotic prophylaxis. Animal models looking at the use of new biodegradable materials to replace antibiotic impregnated poly(methylmethacrylate) bone cement have shown promise in reducing the number of follow-up surgeries, enhancing antimicrobial efficacy, and regenerating bone in an infected defect.²²³

CEREBROSPINAL FLUID SHUNTS

Infection is a major cause of morbidity in children who undergo CSF shunting procedures.^{252,273,477} Such procedures are performed to divert CSF in symptomatic hydrocephalic patients and are used commonly in patients with anatomic abnormalities (e.g., meningomyelocele and Chiari malformations), in premature newborns with intraventricular hemorrhage or intracranial infections (e.g., congenital cytomegalovirus, congenital toxoplasmosis, and bacterial meningitis), and in patients with central nervous system (CNS) tumors or head trauma. Usually the proximal end of the shunt is placed in the frontal or fourth ventricle and the distal end is inserted into the peritoneal cavity (i.e., ventriculoperitoneal shunt). Other compartments such as the right atrium (i.e., ventriculoatrial shunt), the pleural cavity, or the gallbladder can be used to place the distal end. CSF shunts are prone to complications, with a 10-year failure rate greater than 50%.¹²² The most common complication is mechanical (such as obstruction or overdrainage), followed by shunt-related infection. The incidence of shunt-related infection varies considerably, from 0.3% to 26%, with more recent studies reporting a range of 8% to 12%.^{23,70,103,136,188,252,273,286,477} These infections increase morbidity rates and, in some cases, significantly affect patient outcomes. In addition, the increased morbidity caused additional expenses and resulted in higher costs to the health care system.⁵³² Understanding some of the factors that contribute to the development of these infections has helped reduce their incidence.^{141,564}

Epidemiology

Almost two-thirds of shunt-related infections occur within 1 month after placement of the shunt, and 90% of infections are manifested within 6 months.^{187,269,339,459} The incidence of shunt-related infections is significantly higher in infants in the first 6 months of life than in older children or adults.^{133,282,414,553} The infection rate is even higher in newborns with intraventricular hemorrhage who undergo shunting in the first week of life¹⁵ and in premature infants.^{273,340} Reasons for the increased incidence of shunt-related infection in very young patients are multifactorial. Several mechanisms that have been suggested include

delayed wound healing, higher skin density of bacteria that are more resistant to antibiotics and more adherent to the shunt, longer duration of hospitalization, surgical technique, and increased exposure to antibiotics just before the shunt placement.

No significant difference in infection rate is seen in patients with ventriculoperitoneal or ventriculoatrial shunts,^{376,473} but a lower infection rate was noted in those with lumboperitoneal or cholecystic shunts. An increased risk for development of infection was reported for shunts placed immediately after removal of a previously infected shunt, probably because of incomplete eradication of bacteria.^{137,255} Several other factors, including the underlying cause of the hydrocephalus,¹³³ the surgeon's experience,^{96,251} previous shunt infection,³³⁶ the duration of surgery, the number of people in the operating room, perioperative factors (e.g., prophylactic antibiotics, skin preparation, and shaveless operation),⁵¹⁶ operative time, open surgery to insert the abdominal catheter versus direct puncture of the abdominal wall with a trocar, postoperative CSF leakage, and others,^{273,477} have been reported to be associated with an increased incidence of shunt-related infection. Although a trend toward more shunt-related infections has been reported with these factors, it has not been demonstrated consistently. Malignant lesions and trauma as etiologies may have lower rates of infection.⁴⁷⁸ A few studies suggest that tapping the shunt may result in an infection, with an incidence ranging from negligible to greater than 30% in premature infants with shunts tapped multiple times.⁷⁰ Reinfection rate was estimated to be around 25%.^{252,274,528} Multiple factors were suggested as contributing to reinfection, including treatment duration of the first infection, age younger than 6 months, nonsurgical management, intraventricular hemorrhage (IVH) of prematurity, intracranial cysts, or aqueductal stenosis.^{340,477,528} The median time to reinfection (i.e., second episode) ranged from 65 to 90 days.^{274,528} Almost 60% of children with second infection developed a third reinfection, and 47% of them developed a fourth infection.⁵²⁹ The median time to the second infection was 65 days, for the third infection 477 days, and for the fourth infection 2137 days.⁵²⁸

Etiology

Staphylococcal species are the most common cause of shunt-related infection, with coagulase-negative staphylococci (e.g., *Staphylococcus epidermidis*, *S. capitis*, *S. hominis*, and *S. lugdunensis*)¹³⁰ being isolated in 25% to 70% of cases (Table 74.1).^{130,265,282,473} *S. aureus*, the second most common gram-positive bacterium, is responsible for 10% to 40% of cases. Streptococci (e.g., viridans, group B or C, *S. pyogenes*, *S. pneumoniae*, enterococci) are identified less commonly (3–7%). Other gram-positive bacteria such as *Propionibacterium*^{282,518} and *Corynebacterium* (diphtheroids)^{25,180} are isolated as well. The seemingly increased incidence of shunt-related infections caused by these two groups of bacteria probably is the result of poor culture technique (e.g., failure to use anaerobic culture media, less than 5 to 7 days' incubation period), misinterpretation of culture results (e.g., culture contamination) leading to underreporting, or both.

Gram-negative bacteria (e.g., *E. coli*, *Klebsiella* spp., and *Proteus* spp.) together are the cause of 5% to 25% of shunt-related infections.⁴⁹⁶ *Pseudomonas* spp. and *Acinetobacter* spp. are reported as well, but less frequently. Many other etiologic agents, including fungi⁸⁶ (e.g., *Candida*,^{34,163} *Histoplasma*,⁴⁶¹ *Cryptococcus*,²²² *Torulopsis*⁵⁶³), *Pasteurella multocida*,²⁸⁴ *Neisseria* spp.,^{217,503} *Serratia marcescens*,⁶⁷ *Listeria monocytogenes*,²⁹⁰ nontuberculous mycobacteria,⁸² and others, have been reported less commonly as causing shunt-related infections. With the increase in the number of patients who are immunocompromised or have significant risk factors for infection (e.g., neutropenia, chronic intravenous catheters, prolonged administration of broad-spectrum antibiotics, and hyperalimentation), the incidence of these rare infections may increase. Bacteria that traditionally cause meningitis, such as *Streptococcus pyogenes* (group A strep),³⁹² *H. influenzae*,^{472,553} *S. pneumoniae*,^{376,473,556} and *Neisseria meningitidis*,²⁸⁷ have been reported as causing shunt-related infections. Whether these cases were isolated shunt-related infections or extensions of meningitis into the ventricular system (i.e., ventriculitis) is not clear. Therefore if such bacteria are isolated from a suspected shunt and the patient has a communicating hydrocephalus, lumbar puncture should be performed to rule out meningitis. Of interest, most children with

Pathogenesis

Several observations suggest that most CNS shunt-related infections are caused by inoculation of the organism during surgery or bacterial colonization during the early phase of wound healing.⁵¹⁹ Contamination of the device by ward personnel during manipulation also was suggested.^{405,561} These observations include the facts that common skin flora (e.g., coagulase-negative staphylococci and *S. aureus*) are the pathogens most frequently encountered, most of the infections occur within the first few weeks after surgery, and irrigation of the system is a risk factor for the development of infection. Another common mechanism (occurring with gram-negative bacterial infections) is retrograde progression of bacteria from the gastrointestinal tract (i.e., bowel perforation)^{212,439} or from the urinary tract (in the case of a ventriculoureteral shunt).¹⁶⁰ Other mechanisms by which shunts become infected include (1) hematogenous infection in which a distant site of infection produces bacteremia leading to a shunt infection, although rare, and (2) wound or skin infection (e.g., cellulitis or decubitus ulcer) with direct extension from the infection site to the shunt.

The predominant role of coagulase-negative staphylococci and *S. aureus* in CNS shunt-related infection is the result of their being the major constituents of normal cutaneous flora, especially in young children,^{295,465} and their having the ability to adhere directly to the shunt (e.g., *S. epidermidis*) or to host proteins covering the shunt (e.g., *S. aureus*). In addition, coagulase-negative staphylococci (and some *S. aureus* strains) produce large amounts of extracellular slime (i.e., biofilm).⁶⁶ More than 60% of staphylococci isolated from infected shunts produce biofilm.^{117,138,185,592} The biofilm of *S. epidermidis* is a mixture of teichoic acid and protein. Production of biofilm also was reported in corynebacterial infection, which may explain the increasing importance of this organism in CNS shunt-related infections.³⁹ Biofilm facilitates attachment of these organisms to the surface of the shunt and protects the bacteria from the host immune defenses. Once the organisms are attached to the shunt material, they are extremely difficult to remove except by complete replacement of the shunt. In addition, penetration of antibiotic into the biofilm is variable, and the biofilm antagonizes

the antimicrobial activity of some antibiotics, such as vancomycin.^{123,142} Moreover infections caused by nonadherent organisms were significantly more likely to be cured by antibiotics alone (without removal of the shunt) than were infections caused by adherent organisms. Similarly Diaz-Mitoma and colleagues¹¹⁷ found that both obstruction of ventriculoperitoneal shunts and failure to cure the infection with antibiotics alone occurred more frequently when infectious episodes were caused by biofilm-producing coagulase-negative staphylococci. Therefore complete removal of the shunt should be considered in patients with coagulase-negative staphylococci or *S. aureus* infection.

The immature humoral immune system of young infants is not likely to explain the increased incidence of shunt-related infections in patients younger than 6 months because these infants mount anti-staphylococcal antibody responses that are comparable to those of older children.⁴¹⁵ Although levels of immunoglobulins and complement proteins are lower in this young group, levels of these proteins normally are very low in the CSF of older individuals (CSF levels of IgG and IgA are between 0.25% and 0.5% of those in serum). In addition, the types of bacteria causing CNS shunt-related infections are not associated commonly with humoral immunodeficiency states, thus suggesting that humoral protection is less important in CNS shunt-related infections. Little is known about the possible role of reduced tissue immunity in these infections.

The foreign body nature of the shunt apparatus plays an important role in the local host defense defect.⁵⁹ Electron-microscopic findings demonstrate irregularities in catheters, allowing microorganisms to be buried in the catheter. Other mechanisms that may contribute to shunt-related infections include (1) abnormal CSF flow (i.e., not being absorbed by the venous sinuses, thought to be important for prevention of infection in the CNS) and (2) interruption of the blood-brain barrier by the shunt catheter, with the creation of a direct tract between the subcutaneous tissues and the ventricles resulting in significant compromise in host defenses.⁵⁶¹

Clinical Manifestations

The initial signs and symptoms of most patients with shunt-related infections are nonspecific and include mild to moderate fever, malaise, irritability, nausea, vomiting, vague abdominal pain, and headache. With such nonspecific findings, the physician must be careful to differentiate between a potential shunt-related infection and an intercurrent viral or bacterial infection of the upper respiratory, urinary, or gastrointestinal tract. Examination of the CSF (from a shunt tap) may be helpful. Only a minority of patients have the classic signs and symptoms of CNS inflammation, such as a stiff neck, bulging fontanelle, change in mental status, cranial nerve palsy, or papilledema. In some patients the shunt tract may be infected, with evidence of cellulitis, dehiscence, or both of the surgical wounds. Tenderness, edema, or erythema along the tract itself may be the only sign. Patients with known seizures frequently develop seizures with shunt malfunction (inducing in cases of infection).²⁶¹

The type of shunt affects the nature of the infection. For example, ventriculoperitoneal shunt-related infections may cause symptoms and signs confined to the abdominal cavity, such as abdominal pain, tenderness (with or without guarding), intestinal obstruction,⁴³⁵ or spontaneous bacterial peritonitis.^{162,350} Rarely a distal shunt-related infection will be manifested as frank ascites as a result of CSF malabsorption.²⁷⁵ A relatively common complication of ventriculoperitoneal shunts is an inflammatory peritoneal exudate that may lead to CSF loculation and the subsequent formation of a peritoneal pseudocyst.^{17,437} These pseudocysts often are palpable and can be visualized by ultrasonography or CT. Bacteria are isolated in a third of cases, suggesting that infection may play a role in the pathogenesis of pseudocysts. In most cases, however, a high index of suspicion is required because the initial abdominal symptoms occur with no other signs of shunt malfunction.

A unique complication of patients with ventriculoatrial shunts is the development of immune complex disease such as shunt nephritis (a form of acute glomerulonephritis), arthritis, or rash.⁴⁴⁷ In most of these cases, the infecting organism is *S. epidermidis*, but other bacteria such as *Corynebacterium* can cause this complication.⁵⁶ In the case of shunt nephritis, the patient has fever, edema, malaise,

hepatosplenomegaly, hypocomplementemia, anemia, azotemia, hematuria, and proteinuria.¹⁰⁶ Pathologic findings consist of mesangial hypercellularity and granular deposits of immunoglobulins and complement along the glomerular membrane. Rarely arthritis may be the initial symptom.²⁸⁸

Diagnosis

Although shunt-related infections are not common, the nonspecific signs and symptoms and the insidious onset in many cases render establishing a diagnosis difficult. Therefore in any patient with a CNS shunt and fever without an obvious source, a shunt-related infection should be considered, especially in the case of persistent symptoms. A higher index of suspicion for shunt-related infection is needed in young patients with new fever within 3 to 6 months after shunt placement. The only definitive diagnostic test is direct staining and culture of CSF. Tapping the shunt or sampling fluid in direct contact with the shunt should be performed if no signs or symptoms of increased intracranial pressure are noted. CNS imaging (CT or MRI) is recommended before the tap is done if such symptoms exist. The shunt tap should be performed with careful sterile technique by a practitioner familiar with the technique and underlying hardware.

When percutaneous needle shunt aspiration is performed, the area around the shunt valve or reservoir should be sterilized and butterfly needle inserted. Measurement of opening pressure can help diagnose a distal malfunction (increased pressure) or proximal shunt obstruction (less than expected pressure). Gentle aspiration of CSF sometimes is performed if no fluid returns spontaneously. If only a few drops of CSF can be obtained, the more important tests, Gram stain and culture, should be performed first.

CSF should be tested for glucose concentration, differential cell count, Gram stain, and culture. Protein concentration is requested often but is of very limited help in evaluating the presence or absence of an infection because high protein levels are found in many patients with shunt malfunction and no infection. In contrast, normal protein levels have been reported in many patients with shunt-related infections. A low glucose level suggests an infection, although this is not sensitive for shunt-related infection. Typically CSF pleocytosis with a predominance of PMNs is indicative of a shunt-related infection. A count of 100 cells/ μ L or more is highly suggestive of infection.^{281,291,337} According to one study, a CSF WBC count greater than 100 cells/ μ L with more than 10% PMN cells in febrile patients is 82% sensitive and 99% specific for shunt infection, with a positive predictive value of 93%.³³⁷ In contrast, the negative predictive value is 95% for a sample with less than 10% PMNs. A recent review suggests that infection with gram-negative bacteria resulted in a higher initial and peak WBC count, with a greater percentage of PMNs than gram-positive bacteria.¹⁵⁶ In some cases the finding of a positive CSF culture is interpreted as a shunt-related infection despite a normal WBC count (<10 WBCs/ mm^3) and the absence of clinical symptoms, when the positive culture probably represents colonization or contamination. Other cells, such as mononuclear cells^{269,497} or eosinophils^{337,571} can also predominate during an infection. If eosinophilia is the predominant cellular response, an allergy to the shunt (e.g., silicone²³⁴) or the materials used for sterilization (e.g., ethylene oxide⁴¹¹) or use of an antibiotic-impregnated catheter⁵²⁹ or intraventricular administration of antibiotics (e.g., gentamicin³⁴⁹ and vancomycin¹⁷⁷) should be considered. It is important to note that eosinophilia (without these causes, including infection) is relatively common (but transient) in children with a CNS shunt.^{155,194}

Interpretation of the WBC count should be done cautiously if the red blood cell count is high because the increased number of WBCs can be the result of blood spilling into the CSF or be part of the inflammatory response to the presence of blood (i.e., chemical ventriculitis).⁴⁰⁶ A negative Gram stain result does not exclude an infection, and one should wait for the results of culture. Ventricular fluid always should be cultured anaerobically as well as aerobically. Although most bacteria causing shunt-related infections grow within 48 to 78 hours, cultures should be held for 7 days (if still negative) for fastidious organisms such as *Propionibacterium*.²⁷ The possibility of contamination or colonization of the shunt without infection should be considered when the culture is positive but other CSF parameters are normal. If such a scenario occurs and bacteria are growing only from one sample (e.g.,

a shunt tap) and not from subsequent CSF cultures, a shorter course of therapy may be sufficient.

Blood cultures, a peripheral complete blood count (CBC), and ultrasound of the abdomen (for ventriculoperitoneal shunts) are of limited value. For example, although 90% of patients with ventriculoatrial shunt-related infection will have a positive blood culture, fewer than 10% of patients with other shunt-related infections will have a positive culture. In more than a third of patients with shunt-related infections, no elevation in the peripheral WBC count was found. Some investigators suggest that blood CRP levels may be helpful in establishing the diagnosis of shunt-related infection when other concurrent infections (e.g., sinusitis, pneumonia) were excluded.^{281,456} The triad of fever, abnormal CSF WBC count, and greater than 5% eosinophilia is highly predictive of a shunt-related infection.³³⁷

Treatment

A variety of medical and surgical approaches to treatment of an infected shunt have been suggested.⁵⁷⁰ Regimens include (1) the use of antibiotics (systemically, with or without intraventricular administration) without removal of the shunt hardware; (2) removal of the infected shunt followed by immediate insertion of a new shunt and the administration of antibiotics³⁶⁶; (3) removal of the infected shunt and insertion of an extraventricular device (EVD) to monitor the patient's response to the accompanying antibiotic therapy, with a new shunt inserted only when the ventricular system is sterilized; (4) removal of the infected shunt followed by a stereotactic third ventriculostomy and administration of antibiotics; and (5) externalization of only the distal (e.g., peritoneal) catheter, along with the administration antibiotics.

The use of antibiotics alone without surgery was justified by the need to maintain CSF drainage and avoid costly operations and lengthy duration of hospital stay. The low success rate of this approach (33%) and the higher mortality rate associated with it suggest that it should not be used (Table 74.2). Of interest, the failure rate was much higher with infections caused by biofilm-producing organisms than with infections caused by bacteria that do not produce biofilm.¹¹⁷ Only in shunted patients with purulent meningitis caused by *S. pneumoniae*, *N. meningitidis*, or *H. influenzae* did the administration of systemic

antibiotics alone without removal of the shunt seem to be an effective option.^{287,381}

Combining immediate replacement of the infected shunt with a new shunt and antibiotic therapy has a higher rate of success (70%; see Table 74.2) than does the use of antibiotics alone. Nonetheless it is less effective than removal of the infected shunt accompanied by insertion of an EVD and administration of antibiotic therapy (88% success rate; see Table 74.2). A decision analysis of 17 studies reached the same conclusion and suggested that "this treatment option has the highest cure rate and the lowest failure and mortality rates."⁴⁵⁵ In addition, lack of the ability to monitor when the ventricular fluid is sterilized results in a longer period of systemic antibiotic therapy (e.g., 4 to 8 weeks) and may lead to an increase in iatrogenic infections and cost.

For infection that involves only the distal part of the shunt (e.g., pseudocyst, appendicitis,³⁹⁵ erythema or swelling along the shunt tract, or surgical wound infection), externalization of only the distal end of the shunt along with the administration of antibiotic therapy is recommended by some neurosurgeons. Potential advantages of this technique include (1) diversion of CSF from an infected area to avoid ascending infection, (2) maintenance of CSF flow to prevent increased intracranial pressure (ICP), (3) the ability to perform frequent CSF sampling, and (4) the capability of monitoring therapy. The disadvantage is that early infection or colonization of the proximal portion of the shunt may be obscured by the antibiotic treatment and become active after discontinuation of therapy and reinsertion of the distal part. In patients with *P. acne*-related distal shunt infection, catheter removal without (or very short) antibiotic treatment is sufficient.²⁷

Internal shunting by a third ventriculostomy with avoidance of a prosthetic device during the infected CSF shunt removal was investigated as another option to reduce reinfection. Although this procedure was shown to be effective in managing patients with refractory shunt-related infections who have a noncommunicating hydrocephalus, patent subarachnoid space, and adequate CSF absorption, the prevention of reinfection was marginal.^{149,332,368,470,473} Yet it seems that the reinserted ventriculoperitoneal shunts after a third ventriculostomy have a better longevity than those inserted without this procedure.⁴⁷⁰ Shunt independence for extended periods was documented in patients without

^aWith and without intraventricular antibiotics.

EVD, Extraventricular device.

myelomeningocele. The success rate is lower in those with myelomeningocele or hemorrhage or after meningitis.¹³⁵

The most effective treatment of shunt-related infections is to remove the entire infected shunt and insert an EVD to control ICP and monitor the infection. After antibiotic therapy has been successful, a new shunt is placed. With this approach, treatment success is very high (see Table 74.2), with more rapid clearance of the infection and a shorter duration of therapy.

The choice of intravenous antibiotic depends on local patterns of antimicrobial susceptibility and the ability of the antibiotic to penetrate the blood-brain barrier. With the notable rate of methicillin-resistant staphylococci, vancomycin should be used as initial therapy while awaiting bacteriologic identification and the results of antibiotic sensitivity testing. Effort should be made to discontinue vancomycin promptly following proof that organism is sensitive to the semisynthetic penicillins. In addition, despite *in vitro* data that bacteria are highly sensitive to first-generation cephalosporins (e.g., cephalothin, cefazolin), they should not be used due to poor penetration of the blood-brain barrier. Linezolid has been used successfully in cases of shunt infection.^{54,79,372,548,589} This drug has a good CSF penetration, with concentrations above the minimal inhibitory concentration (MIC) of most gram-positive bacteria, including MRSA.^{40,591} The limited data available suggest that linezolid should be considered cautiously when vancomycin fails or cannot be given. Rifampin should be considered as one of the drugs in the combination for gram-positive bacteria for three reasons. First, most staphylococci are still sensitive to this antibiotic and their MIC is significantly lower than that of other antistaphylococcal drugs. Unfortunately the use of rifampin alone may be followed rapidly by rifampin-resistant variants. Second, rifampin penetrates CSF well and easily achieves a greater than 10-fold level over the MIC of most staphylococci. Third, rifampin has demonstrated good bactericidal activity even when staphylococci were embedded in biofilm. In contrast, staphylococcal biofilm inhibits the antimicrobial activity of vancomycin.¹⁴²

To achieve more consistent and efficient eradication of bacteria, the CSF drug level should be at least 10 times higher than the MIC of the pathogen. Therefore the dosage of antibiotic or antibiotics and the dosing interval should be maximized (i.e., “meningeal schedule”). If the selected antibiotic does not clear the infection within 2 to 3 days and no improvement occurs in CSF biochemical and WBC parameters (i.e., seemingly inadequate control of the infection), measurement of the bactericidal titer of ventricular fluid should be considered. To determine bactericidal titer, 1 mL of CSF (if CSF production is >5 mL/h) at the expected peak antibiotic level (i.e., 2 to 3 hours after the antibiotic is given parenterally) is diluted serially with culture media to produce dilutions of 1:2, 1:4, 1:8, and 1:16. To these dilutions, an equal amount of medium with 10⁵ colony forming units/mL of the offending bacteria is added (the final CSF dilution is 1:4, 1:8, 1:16, and 1:32). After 24 hours of incubation, the tubes are observed for turbidity, which reflects the growth of bacteria. If no turbidity is seen in the 1:8 and 1:16 or higher dilution tubes, the CSF level of the antibiotic probably is sufficient, and continued growth of bacteria from CSF may be caused by colonization of the EVD or contamination. On the other hand, if turbidity is noted in the tube with less than a 1:8 dilution (i.e., a 1:4 dilution), the CSF level of antibiotic may not be sufficient to combat the infection and the addition of another antibiotic or change to a different antibiotic is warranted.

Selection of the initial antibiotic before culture results are known can be based on the patient's clinical and CSF findings. The initial diagnostic step after empiric antibiotic therapy is evaluation of the CSF Gram stain. If the Gram stain result is positive for gram-positive bacteria (e.g., *Staphylococcus* or *Streptococcus*), the drug of choice is vancomycin. If the Gram stain shows gram-negative bacteria, the drug of choice is cefotaxime (or ceftriaxone) or, in cases of suspected pseudomonas or multidrug-resistant infection, meropenem. Treatment with an aminoglycoside is acceptable, but the outcome seems to be less favorable because of poorer penetration into CSF.³⁸⁶ If the Gram stain result is negative, other CSF parameters (e.g., WBC count and glucose) should be examined. If either is abnormal and the patient is not severely sick, vancomycin alone may be considered because the chance of having a gram-negative infection is low.⁴⁹⁶

In contrast, if the patient is more ill, coverage for gram-negative bacteria should be added (e.g., cefotaxime or ceftriaxone). In nontoxic patients with normal CSF parameters and no distal symptoms (e.g., peritonitis or wound or tract infection), antibiotic therapy can be withheld until the results of culture are known. On the other hand, if distal signs or symptoms exist, therapy is tailored according to the site. In patients with skin involvement, vancomycin is the drug of choice, whereas in febrile patients with abdominal symptoms, the combination of cefotaxime (or ceftriaxone) and metronidazole (to cover anaerobic bacteria) is preferred. An alternative for gram-negative plus anaerobic coverage in a seriously ill patient with history of broad spectrum antibiotic exposure or multidrug-resistant organism is meropenem.

Direct instillation of antibiotics into the ventricular system to increase their levels is suggested by some experts.⁵⁹⁵ Such treatment may be considered in patients with persistently positive cultures despite intravenous therapy or multidrug-resistant organisms requiring specific antibiotics with inadequate CSF penetration. Several studies have reported promising results using combination of intravenous and intraventricular therapy.^{132,303,512} Unfortunately the suggested doses for intraventricular treatment have been determined empirically on only a small number of patients, and their pharmacokinetics and pharmacodynamics have not been studied well. This therapy is not without risk, especially when the recommended doses often are much higher than those found to cause neurotoxicity.^{262,481,566} Pleocytosis and eosinophilia also have occurred in patients receiving intraventricular vancomycin³⁰⁷ or gentamicin.³⁴⁹ In addition, preservative-containing preparations should be checked for appropriateness for intraventricular instillation. Limited pharmacokinetic data suggest that clearance of the instilled intraventricular antibiotic is sufficiently slow to allow once-daily administration. If possible, the EVD should be closed for 30 to 60 minutes after the drug is administered. If the EVD cannot be closed and the amount of CSF drainage exceeds 7 to 10 mL/h, the frequency of intraventricular antibiotic instillation should be increased to twice daily.

Antibiotics commonly recommended for intravenous and intraventricular use according to the etiologic agent are shown in Table 74.3, although antibiotic choice should be based on antimicrobial susceptibility results of the isolated pathogen. A small study in adults showed that administration of vancomycin 10 mg intraventricularly once daily was safe and achieved levels greater than 5 µg/mL (the recommended CSF trough level needed to achieve cure) for up to 21 hours.⁴⁰⁷ Because of the potential toxicity of the empirically recommended intraventricular antibiotic doses and the unpredictability of CSF levels, irrigation of the ventricular system with a known concentration of an antibiotic solution is preferred when systemic antibiotics fail to eradicate the bacteria. To achieve irrigation, two EVDs must be inserted to produce a continuous flow of solution. The concentration of antibiotic in the solution should be equal to the highest safe plasma level when the drug is given intravenously. For example, for treating gram-negative bacteria sensitive to amikacin, amikacin at a dose of 30 to 40 mg/L of saline solution (producing a concentration of 30–40 µg/mL) is recommended. Gentamicin 10 to 12 mg/L (using a special intrathecal preparation) is an acceptable alternative when the gentamicin MIC for the bacteria is less than 1 µg/mL. The antibiotic solution is administered through one EVD at a rate of 10 mL/h, and the second EVD is left open to drain the fluid and to remove debris and pus from the ventricles.

When antibiotic therapy is completed, abnormal CSF findings such as low glucose or mildly elevated protein or cell counts should not delay reshunting. The duration of treatment is empirical and depends on the etiologic agent, the CSF parameters at initial evaluation, and the time to sterilization. In our institution, we found the following schedule to be successful: If CSF parameters are *normal* but culture yields coagulase-negative staphylococci from only the operating room (i.e., the initial sample), therapy should be given for only 3 to 4 days. If subsequent cultures also are positive, therapy should continue until negative cultures have been obtained for 7 days. If CSF parameters are *abnormal* in the operating room and culture is positive *only* from that specimen, therapy should continue for 7 days. If subsequent samples show abnormal CSF findings and positive cultures, therapy should be extended until negative cultures have been obtained for 10 days. This protocol was adopted by the Infectious Diseases Society of America guidelines for the management of CSF shunt infections.⁵³⁰

TABLE 74.3 Recommended Intravenous and Intraventricular Antibiotic Therapy for Shunt Infection According to Etiologic Agent

Etiologic Agent	Antibiotic	IV Dose (mg/kg/day) and Frequency	Intraventricular Dose (mg/day, 1 Dose)
Bacteria			
<i>Staphylococcus aureus</i> or coagulase-negative staphylococci Methicillin sensitive	Oxacillin ^{a,b} or Nafcillin ^{a,b}	200 (q8h) 200 (q8h)	NA 50–75
Methicillin resistant	Vancomycin ^b or Linezolid	60 (q8h) 30 (q8h)	5–20
Streptococcal species	Penicillin ^a or Ampicillin ^a	200,000/U (q6h) 400 (q6h)	NA 10–25
Diphtheroids <i>Enterococcus faecalis</i>	Ceftriaxone Ampicillin ^a or Penicillin ^a plus Aminoglycoside ^c	100 (q12h) Doses as above	NA
Anaerobic bacteria	Metronidazole	22.5–30 (q8h)	NA
<i>Escherichia coli</i> , <i>Klebsiella</i> , <i>Proteus</i> , <i>Enterobacter</i>	Cefotaxime or Ceftriaxone or Amikacin ^s or Tobramycin ^d or Gentamicin ^d or Meropenem	200–300 (q6h) 100 (q12h) 22.5 (q8h) 7.5 (q8h) 7.5 (q8h) 120 (q8h)	NA NA 5–30 5–20 1–8
<i>Pseudomonas</i> spp.	Ceftazidime or Aminoglycoside plus Broad-spectrum penicillin or Carbapenem	200 (q8h)	NA
Fungi			
<i>Candida</i> spp.	Amphotericin B ^e AmBisome	1 (q24h) 5 (q24h)	0.1–0.5

NA, Not available.

^aIn patients allergic to penicillin, use vancomycin.

^bIf cerebrospinal fluid levels are not sufficient and the bacteria are sensitive to rifampin, add rifampin, 20 mg/kg per day divided every 12 hours.

^cSee doses (for the specific aminoglycoside) for treatment of *E. coli* below.

^dThe addition of a broad-spectrum penicillin (e.g., piperacillin or ticarcillin, 300 to 400 mg/kg per day divided every 6 hours) may add to the bactericidal activity.

^eIf ventricular fluid remains positive after 5 to 7 days of therapy with amphotericin, add flucytosine (150 mg/kg per day divided every 6 hours).

A longer duration of antibiotic therapy is recommended with other bacteria (e.g., *S. aureus*, gram-negative bacteria). If culture is positive *only* on samples from the *operating room* and CSF findings are normal, treatment should be given until negative cultures have been obtained for 7 days. In all other situations, therapy should continue until negative cultures have been achieved for 10 days. Reshunting should take place immediately at the end of treatment. No benefit is found in observing the patient for a time without antibiotics for relapse of the infection.⁵⁶⁴

Complications

Shunt-related infections are associated with increased morbidity and mortality rates.⁴⁸¹ Patients with shunt-related infection have an increase in shunt-related operations, which contributes to the increased morbidity and cost. Even when the initial infection is treated successfully, secondary infection (or contamination) of the EVD occurs in 5% to 10% of cases.

To minimize the risk for development of a secondary infection, a sterile closed-drainage system should be maintained. Only trained personnel should be allowed to drain CSF samples from the system, and injection into the system should be avoided. Continuous external drainage of CSF also causes loss of electrolytes and fluid. Therefore assessment of serum electrolytes is recommended, and, if significant, the total daily amount of drained CSF should be replaced. Recurrent shunt-related infection after completion of treatment is common, with two-thirds of such infections being caused by the same organism.²⁵² Unusual complications of ventricular shunt infections include brain abscess and subdural empyema.^{136,558}

Prognosis

Complete removal of the shunt system results in better prognosis.⁴⁷⁷ Long-term morbidity occurring after a shunt-related infection includes seizures, psychomotor retardation, and cognitive deficiency. The intelligence quotient (IQ) scores of children with myelomeningocele who

had a shunt-related infection were found to be significantly lower (mean IQ, 72) than the scores of children with shunts but no infection (mean IQ, 95).³⁴² A trend was observed in which younger children with shunt-related infections had a lower IQ than older children with shunt-related infections, especially if the infection was caused by gram-negative bacteria. In addition, shunt-related infection adversely affected school performance.⁵⁵³ With appropriate combined medical and surgical therapy, the mortality rate from shunt-related infection is low, but any episode of shunt-related infection appears to increase the probability of a subsequent episode.

Prevention

Standardized care protocols have been shown to reduce infections.^{213,253,410,489} Preventive measures to reduce the incidence of shunt-related infection include attention to preoperative and intraoperative technique and the prophylactic use of antibiotics. Bactericidal shampoos (e.g., chlorhexidine) should be used to reduce the bacterial density of the scalp before surgery is performed. Shaving the scalp seems to be a risk factor, and thus shaveless surgery should be considered.²¹⁶ During the operation, only essential personnel should be present, and the skin should be cleaned with a fat solvent, followed by iodine solutions that reduce the number of bacteria⁸⁷ or bacteria's ability to adhere to the shunt (bacitracin).¹⁷⁶ Careful attention should be paid to surgical technique, with contact between the shunt and the skin avoided. A detailed preoperative protocol developed by the Hydrocephalus Clinical Research Network (HCRN) has reduced the infection rate from 8.8% to 5.7%.²⁵³ Other investigators were able to reduce the infection rate by using measures similar to those suggested by the HCRN.⁸⁸ A single-center study showed that infection rate was reduced from 21% to 4.3% when impregnated sutures were used,⁴⁷⁸ and other studies suggest that use of an antibiotic-impregnated shunt system significantly reduces the incidence of shunt infections in contrast to the use of a standard shunt.^{175,362,390,396,462,463,593} However, no significant reduction in the overall shunt-related infection rate was observed in other studies.^{193,242} In addition, the antibiotic-impregnated catheter may increase the rate of bacteria resistant to its antibiotic components.¹¹⁵ Large, prospective, randomized studies are needed to evaluate the real contribution of an antibiotic-impregnated shunt to the reduction in infection rate.

Multiple studies have examined the effect of prophylactic antibiotics for the shunt insertion procedure on reducing the infection rate.^{65,263,282,420,426,427} A recent meta-analysis and systematic review of nine studies, with seven being randomized controlled trials, found the infection rate in the prophylactic antibiotics group to be 5.9% compared with 10.7% in the control group.²⁶³ A previous meta-analysis of 17 trials found a statistically significant benefit for either systemic antibiotic prophylaxis (15 studies) or antibiotic-impregnated catheters (two studies) in reducing the incidence of shunt-related infections, and some experts suggested adding intraventricular antibiotic administration (e.g., gentamicin or vancomycin) during the procedure.^{421,426} The choice of antibiotics should be based on the local antibiotic sensitivity pattern of the pathogens commonly causing shunt-related infections in that area, although cefazolin is generally recommended, with vancomycin or clindamycin recommended in cases of β -lactam allergy and vancomycin preferred by some due to the frequency of coagulase-negative staphylococcus in these infections. Although many experts recommend giving the first dose 30 to 60 minutes before skin incision, prophylaxis should be considered to start 8 to 12 hours before surgery to allow higher levels of drug to accumulate in skin tissue than would do so if treatment were given just before the operation. The duration of prophylaxis should not exceed 24 to 36 hours. Further studies are needed to identify factors important in the development of shunt-related infections so that better techniques can be developed to further reduce or even eliminate this devastating complication of CNS shunting.

INTRACRANIAL PRESSURE MONITORS

Monitoring of ICP has become an important part of the evaluation, treatment, and management of children with a variety of intracranial pathologic processes,³⁰⁸ including congenital anomalies (e.g., cranial or craniofacial dysostosis), metabolic diseases, trauma, intraventricular or

subarachnoid hemorrhage, intracranial infections (e.g., meningitis, encephalitis), and other ischemic or hypoxic insults.³⁸⁸ Several studies have demonstrated the therapeutic and prognostic benefit of monitoring ICP in children with high ICP^{150,233,296,520}; nonetheless this procedure is not without complications such as hematoma, bleeding, leakage of CSF, and infection. Infections for which monitoring of ICP is used include ventriculitis, meningitis, brain abscess, subdural empyema, skin infection, and cranial bone infections.^{264,307,580}

Several methods are available for monitoring ICP. Intraventricular placement of a catheter with the distal end connected to a pressure transducer is the method used most frequently because of its accuracy and ease of calibration. This procedure also allows drainage of CSF for biochemical or dynamic testing. Disadvantages of ventriculostomy are penetration of the meninges and brain, technical difficulties if the ventricles are small, and greater risk for the development of infection. Other methods used to monitor ICP include a subdural bolt or catheter (only the meninges are penetrated, but the brain remains intact), an epidural transducer (the dura remains intact), and a continuous intraparenchymal monitor (i.e., a fiberoptic cable is inserted through the dura into the brain parenchyma, not intraventricularly). Although both the epidural transducer and the intraparenchymal monitor have fewer complications (e.g., infection) than the intraventricular devices, they are prone to inaccuracy, which limits their use. Selection of the appropriate ICP-monitoring method depends on the patient's condition and the risk associated with the procedure.³¹⁵

Epidemiology

Assessing the true infection rate of ICP monitoring devices is very difficult, mainly because the methods used to define infection (i.e., inclusion and exclusion criteria), the indication for ICP placement, and antibiotic use vary widely among reported studies. The incidence of infection ranged from less than 1% to 45%, with an average infection rate of 9.5%.^{256,306,579} A much higher rate of infection was reported in patients who had devices that penetrated the meninges²⁰⁸ than in those who had parenchymal monitors.⁴¹⁶

Multiple factors were suggested as increasing the risk for development of ICP device-related infection including intraventricular or subarachnoid hemorrhage, open head trauma, perforation of the dura, CSF leak, neurosurgical procedure, pressure greater than 20 mm Hg, and frequent manipulations of device.¹⁹⁸ Patients with intracerebral hemorrhage usually do not have a higher risk for acquiring infection than those without such hemorrhage. In contrast, if the bleeding is intraventricular, the incidence of infection increases. The rate of infection also is higher in patients with open head trauma than in those with closed head trauma or intracranial malignancy.²¹⁸ Neurosurgical operations contributed significantly to the risk for acquiring infection,^{250,397} and the same was noted if ICP was greater than 20 mm Hg.

Interruption of the monitoring system's integrity (e.g., CSF leak, number of times that the system was open, malfunction, and irrigation) was identified by several investigators as increasing patient risk for acquiring infection.^{85,203,313} The effect of the duration of monitoring on the risk for infection is controversial, especially in patients with ventriculostomy catheters. Although several studies found a correlation between the length of time that the monitoring device was in place and the infection rate,^{256,306} some investigators found no relationship with the duration of monitoring.⁵⁷⁹ The different conclusions probably were the result of differences in the populations studied, the types of devices used to measure ICP, the definitions of infection, and analyses of the data. A critical review of the literature evaluating 23 major studies found a correlation between the duration of ICP monitoring and the rate of infections.³⁰⁶

The need to replace the device at a certain time has been challenged. Analysis of the outcome in 584 patients (receiving 712 ventriculostomy catheters) who had 61 infections showed a steady increase in the daily incidence of infection that peaked at day 10 with an average time to onset of infection 6.8 days.²⁰⁸ These data suggest that the majority of infections occurred early after the ICP insertion and therefore that ICP monitoring devices should be removed as quickly as possible, but, if prolonged monitoring is required, catheter exchange is not indicated.

Etiology

In general, the microorganisms that cause infections related to ICP monitoring devices are the same as those causing CNS shunt-related infections (see Table 74.1). The major difference is that gram-negative bacteria are isolated more often in ICP monitor-related infection than in CNS shunt-related infections.^{302,313,450} The more common bacteria include *Enterobacter* spp., *Klebsiella* spp., *S. marcescens*, and *Acinetobacter* spp. These bacteria are found in water and cause widespread colonization of hospitalized patients. Colonization of the respiratory tract is an especially common occurrence in patients in the intensive care unit and in those with serious underlying disease. Thus these organisms are occurring increasingly frequently in ICP monitor-related infections. Few infections are caused by *Corynebacterium*, *Propionibacterium*, and fungi.^{186,452}

Clinical Manifestations

ICP monitor-related infections often occur in patients with an altered sensorium; therefore the signs and symptoms of meningeal irritation usually are not present. The clinical diagnosis is complicated further by the fact that these patients frequently are critically ill, and their signs and symptoms are caused by the underlying condition and are not a result of the ICP monitor-related infection. In addition, they may be receiving multiple antibiotics for other sources of infection (e.g., pneumonia, bacteremia, or urinary tract infection), both nosocomial and nonnosocomial. Although fever is the most frequent indication of infection, the presence of infections or inflammatory processes at other body sites causes the predictive value of fever to be low. Therefore providing close follow-up, having a high index of suspicion, and obtaining frequent cultures of CSF when available (e.g., ventriculostomy device) are recommended.

Diagnosis

The predictive value of the peripheral WBC count and differential count are very low, and the diagnostic specificity of the CSF parameters is questionable.^{407,450} CSF biochemistry (i.e., protein and glucose) has a very low predictive value. Although a low glucose level may be of help in establishing the diagnosis, a normal level does not exclude the possibility of an infection. Calculation of the ratio of leukocytes to erythrocytes in CSF versus their ratio in peripheral blood was suggested as a potential diagnostic tool for early infection, but it was not validated in a subsequent study.^{407,450} Most patients with ICP monitor-related infection will have an increased CSF WBC count with a predominance of PMNs, but in cases with low growth of bacteria, no elevation in CSF WBC counts ($<10/\text{mm}^3$) was reported. Most of these cases were caused by coagulation-negative staphylococci. In such cases, if no other indicators of infection (e.g., clinical symptoms or low glucose) are present, the possibility that the positive cultures represent colonization or contamination should be considered before treatment is initiated.

Treatment and Prophylaxis

Only a few control trials have evaluated treatment strategies for ICP infection; therefore the same principles used for the management of CNS shunt-related infections can be applied to infections associated with ICP monitoring devices. The use of antibiotics alone without removal of the device may be adequate for the treatment of infections associated with devices placed in the subdural or epidural space unless an abscess or empyema has formed. In the case of ventriculostomy, the infected device should be removed and appropriate antibiotic therapy instituted. Because gram-negative bacteria may also cause ICP device-related infections, initial antibiotic therapy should include both vancomycin and cefotaxime or ceftazidime if the Gram stain is negative. When the etiologic agent is identified, the specific antibiotic or antibiotics can be chosen from those listed in Table 74.3. The optimal treatment for fungal infections is unknown. Clinical experience with amphotericin B suggests that it is effective despite the fact that it achieves low levels in the CSF. Because fluconazole and voriconazole are known to achieve the best CSF levels, they should be considered as the first drugs of choice.²⁵⁴ The duration of therapy depends on the etiologic agent and the CSF parameters. In patients with positive CSF culture but minimal

CSF pleocytosis, if the CSF culture becomes negative immediately after removal of the catheter, therapy should be given for only 3 or 4 days because the cultures before removal of the catheter reflect colonization and not infection. If subsequent cultures are positive, therapy should continue for 10 days of negative cultures.

Although removal of the ICP monitor (if >5 days) and reinsertion at an alternative site was recommended as a prophylactic approach to reduce the infection rate, this practice is controversial, and several studies showed that routine changes of the ICP monitor did not reduce the risk for development of infection.^{306,582}

Many physicians use prophylactic antibiotics for the duration of ICP monitoring in the hope of preventing infection. Unfortunately those studies that have evaluated the utility of antimicrobial agents in preventing such infections reported contradictory results.⁴³¹ A decreased rate of ICP monitor infection was reported in patients who received prophylaxis for the duration of the ICP monitoring, but these patients had an increase in MRSA and *Candida* infections.⁴¹³ Yet other studies showed no benefit of either preprocedural only prophylactic antibiotics or combined with prolonged antibiotic therapy (until the device was removed).^{10,77} In addition, broad-spectrum antibiotic prophylaxis was associated with a shift to resistant gram-negative pathogens.³³¹ Observational studies suggested that use of antibiotic-coated devices significantly reduced infection rates,³⁶¹ and the same results were seen in a longitudinal study comparing infection rates in patients with and without antibiotic-coated catheter.¹⁹² In contrast, a retrospective analysis of patients who developed ventriculitis after placement of either antibiotic-coated EVD or non-antibiotic-impregnated EVD found no major advantage for the impregnated device.⁴⁸⁷ A recent systematic review of all studies evaluating systemic prophylactic antibiotic throughout the duration of the external ventricular drainage or placement of antibiotic-coated devices concluded that there is probably some benefit to using either of them.⁴⁸⁸ The varying quality of the reviewed studies (most nonrandomized) suggests that cautious interpretation and further research is needed to confirm these findings. In the meantime, antibiotic-impregnated catheters (with or without systemic antibiotics) should be considered for prophylaxis.

INTRATHECAL PUMP INFUSION DEVICES

The intrathecal pump infusion system currently is used to infuse morphine to treat refractory pain,³⁷⁸ deliver baclofen (a γ -aminobutyric acid agonist), or treat spasticity of spinal or cerebral origin.^{8,26,399} In addition, patients with generalized dystonia also benefited from intrathecal baclofen.⁷ Several pump systems are used. The simpler systems consist of an externalized catheter system similar to the Hickman catheter¹²³ or a subcutaneous reservoir system similar to an intravascular implanted port. The more sophisticated systems include a programmable pump that usually is implanted in an abdominal subcutaneous pocket and connected via a subcutaneous catheter to the subarachnoid space.⁴¹ An optional sideport in some of these implanted pumps allows aspiration of CSF from the subarachnoid space.

Complications of the intrathecal pump system are relatively rare events^{171,542} and include CSF leakage, intracatheter mechanical complications,⁵¹⁴ pump malfunctions resulting in baclofen withdrawal or overdose, skin necrosis,^{159,514} and infection. Complications (especially wound complications such as CSF fistula, dehiscence, granuloma formation, and infection) occur more frequently in children than in adults.^{10,148,542} Overdose that may result in coma, respiratory depression, apnea, cardiac conduction abnormalities, hypotension or hypertension, and abnormalities of the pupils was reported as well.⁴⁰² Intrathecal baclofen can induce both recurrent and new-onset seizures.^{26,267} In addition, acute withdrawal syndrome was reported when treatment was stopped.⁴⁷⁵ Infectious complications included suppuration at the exit site,^{73,125,207} along the subcutaneous catheter (tunnel infection),^{41,73,125,207} and around the pump,^{41,73,84} or more severe deep-seated and organ space infections.

Epidemiology

The infection rate of intrathecal pump infusion devices ranges from 1.2% to 12%,^{22,60,148} although a recent study reported a rate as high as 21.8%.¹⁶⁴ A more accurate description of the incidence would be the

infection rate per 1000 catheter-days, which ranged from 0 to 2.5. The incidence of infections can be reduced by using perioperative antibiotic prophylaxis.^{60,360,443}

Infections occurring less than 30 days from operative procedure were more likely to involve the skin and soft tissues, whereas those occurring more than 30 days post procedure were more likely to be deep incisional or organ space infections. Factors associated with infection are duration of procedure (>100 minutes)⁷³ and spasticity associated with underlying traumatic brain injury or genetic disorder being the indication for device implantation.¹¹⁸ Multiple other factors, such as patient age, immune deficiency, other concurrent infections, previous intrathecal catheter, number of pump refills, intraspinal anesthetics, surgeon experience with the procedure, and operative complications (e.g., operative loss of blood), were not associated significantly with an increased risk for the acquisition of infection.⁷³ Very thin or malnourished patients may be prone to poor healing or skin breakdown, although a recent study did not find being underweight to be a risk factor for infection. This study also did not find a difference between subfascial versus subcutaneous pump implantation, whereas other studies have noted decreased infection in subfascial pump implantation.^{118,359} One study reported an increased infection frequency in children with a percutaneous endoscopic gastrostomy (PEG) tube or urinary or fecal incontinence.¹⁴⁸ Pump replacement has also been reported as a risk factor for infection following the second operation.³⁵⁹

Etiology

The most common bacteria causing intrathecal device-related infection are from the skin flora. Coagulase-negative staphylococci and *S. aureus* lead the list, but *Streptococcus mitis*,^{73,371} *Streptococcus* group A or G,⁷³ *Corynebacterium striatum*,⁷³ *Enterococcus faecalis*,¹⁵⁶ and polymicrobial infections are observed as well.^{42,118} In addition, several studies have reported gram-negative bacteria as the cause of the pump-related infection. Such bacteria include *P. aeruginosa*,^{73,156} *Pseudomonas paucimobilis*,³⁹⁹ *E. coli*,¹²⁵ and *Klebsiella pneumoniae*.³⁹⁸ A rare case of *C. albicans*,¹²⁵ *Mycobacterium* spp.,¹²⁵ and *Acinetobacter baumannii*⁵³⁴ also has been reported. A rare case of baclofen vial contamination with the fungus *Wangiella* that caused infection was reported as well.^{340,399}

Clinical Manifestations

Clinical findings depend on the site of the infection. Patients with more severe infections (i.e., epidural abscess or meningitis) may have symptoms of these infections (e.g., fever, irritability, headache, nerve root pain, or meningeal signs). In some patients, pain experienced during the injection may be the clue, but in many patients, a high level of awareness for possible infection is important because they will have nonspecific signs and symptoms.

Exit-site and superficial catheter-related infections usually cause local inflammation (e.g., swelling, redness), tenderness, and drainage. The more serious deep-tract (tunnel) infections are more difficult to assess. Visible inflammation along the tract or a soft fluctuant fluid collection around it may be the only clue. Fever is not always present.

Diagnosis

Performing a complete physical and neurologic examination may be helpful. A routine CBC is relatively unhelpful because leukocytosis is not always present, and screening with ESR or C-reactive protein may help identify inflammation in cases of deep-seated infection. MRI may be useful for diagnosing an epidural abscess and evaluating its extent. The only definitive diagnostic tests are Gram stain and culture of exudate or drainage from the exit site (if available), an aspirate of the fluid collection along the catheter tract if tunnel infection is suspected, or CSF for suspected meningitis. Irrigation of the epidural space with 1 or 2 mL of saline after removal of the pump filter (which should be sent for culture) may help in diagnosing an epidural abscess or empyema. Blood culture may be positive in cases of organ space infections, but is unlikely to be helpful in infections involving skin and soft tissue structures.

Treatment and Prophylaxis

If infection has occurred only at the exit site and the superficial catheter tract, local drainage with aggressive cleansing (i.e., topical antibiotics

and antiseptics) but without removal of the catheter was suggested.¹²⁵ Unfortunately more severe or persistent infections occurred (e.g., deep-tunnel and epidural abscess) in some of these patients⁷³ (in the recent study by Dickey and colleagues, 71% of pump salvage attempts did not resolve and resulted in subsequent pump explantation).¹¹⁸ In addition, failure of “catheter-sparing” treatment also was reported.²⁰⁷ Therefore removal of the catheter should be considered even for mild infections if they do not respond promptly to therapy. In patients with pocket, epidural, and meningeal infections, the intrathecal pump system should be removed as soon as possible and systemic antibiotic therapy initiated (for selection of drugs and doses, see Table 74.3). The duration varies, and there are no trials to suggest a specific regimen, although superficial infections generally receive 7 to 14 days of therapy, whereas deeper infections may receive more than 4 weeks of therapy. With the increasing rate of multidrug-resistant staphylococci and the low CSF levels of vancomycin (only 20–30% of serum levels), linezolid may be considered as an alternative. Linezolid has good CSF penetration (60–70% of the serum level)⁵⁹¹ and has been shown effective in treating severe CNS infections,⁴⁴⁴ including intrathecal infusion pump infection.²⁴¹ In the few reports that suggest successful treatment of severe pump infections (including meningitis) without removal of the pump system,^{63,157,447,542,594} the pathogen was frequently considered to be of low virulence (e.g., coagulase-negative staphylococci) or colonization, which may be the reason for the success. In most of these cases, however, instillation of antibiotics into the reservoir with cautious flushing of the catheter or repetitive local application of antibiotic-impregnated fleece³⁹⁸ was combined with systemic antibiotics. The main reason for the intrathecal administration of antibiotics is to increase the level of drug in the CSF. Before antibiotics are added to the baclofen infusion, their compatibility with baclofen should be verified or tested (vancomycin is compatible and can be used safely according to Zed and associates⁵⁹⁴).

No guidelines exist on how to treat severe infections of intrathecal pump systems, but, in most cases, removal of the pump system while systemic antibiotics are given and then reimplantation appear to be the treatment of choice. In rare cases in which removal of the pump will be detrimental to the patient, a trial of intrathecal administration of antibiotics may be justified, with close observation to ensure that the patient's condition is not deteriorating.

Although many physicians use perioperative (or longer) antibiotics for prophylaxis, their efficacy in preventing infection has not been proved. Therefore prophylactic antibiotics should not be administered for prolonged period (>24 hours) after the operation.
